SUGGESTIONS OF A PLAN OF ORGANIZING A HOSPITAL SYSTEM FOR THE CITY OF NEW YORK.*

BY STEPHEN SMITH, M.D.,

NEW YORK

FOR the following reasons the present seems especially opportune for the discussion of the question, What shall be the hospital system of New York during the twentieth century?

1. There is a growing disposition on the part of the medical profession to prefer and seek the advantages of hospital care and treatment for their patients. 2. Wealthy citizens are contributing more freely to the establishment and support of hospitals than at any previous period. 3. The municipal authorities are contemplating the expenditure of enormous sums of public money on hospitals, viz., $12,000,000, on a monster hospital at Bellevue; $7,000,000 on extension of the Blackwell's Island hospitals; $7,000,000 on hospitals for the Borough of Brooklyn; $2,000,000 on a tuberculosis hospital on Staten Island; $1,000,000 for a public hospital on the west side, and, finally, an incredible number of hospitals is being projected by private individuals.

Hitherto, New York has had no hospital system, and, as a consequence, these institutions, both public and private, have been located, constructed, and managed with slight regard to the necessities of the sick poor, or to healthfulness and economy. The first governmental restraint over the establishment of private hospitals was by an act of the Legislature, 1894 and 1895, requiring the approval of the certificate of incorporation of a proposed hospital by the State Board of Charities. Before approving a certificate the Board establishes, affirmatively, the following facts: 1. The desirability of such hospital at the time and place stated in the certificate. 2. The character, as to responsibility of the proposed incorporators. 3. The financial resources of the proposed incorporation. This law has proved of great importance by preventing the establishment, in undesirable localities, of hospitals, managed by irresponsible persons, and without adequate financial support. The location, construction, and management of the public hospitals are under the control of three independent departments of the municipal government, viz., the Charities, Health, and Bellevue and Allied Hospitals. The private hospitals are under no other governmental supervision than that exercised by the State Board of Charities, as stated above, in approving their certificates of incorporation.

A system of hospital development adapted to the wants of the people of the City of New York, during the twentieth century, must be based on a judicious consideration of the following questions:

(1) **What Will be the Future Demand for Hospital Care for the Sick?**—The experience of the last half of the nineteenth century teaches an impressive lesson as to the future demands of the sick for hospital care and treatment. During the first half of that century, there was but one hospital in the old city of New York, excluding the Almshouse, although the population increased from 60,515 to 515,547. During the last half of the century the hospitals increased to upwards of 70, with an increase of the population to 1,850,093. A similar ratio of increase of hospitals to population occurred in the Borough of Brooklyn. At the present time the efforts of public authorities and private corporations, and citizens to increase hospital accommodations is unprecedented.

The increasing popularity of hospitals is due to the great advance of scientific medicine and surgery in determining more accurately the nature of diseased processes, and the conditions essential to their successful treatment. New methods of analysis and instruments of precision are more and more enabling the students of pathology to discover the ultimate elements of disease. The result has been the identification of large numbers of individual diseases hitherto grouped under one name, and consequently treated in gross. These discoveries have enormously enlarged the field of operative surgery, and multiplied remedial measures that must be applied with the greatest exactness.

As these revelations of the modern requirements of practice are in an early stage of development, we can but conclude that hospitals will become more and more the resort of the sick during the present century. Already the conditions of success in surgical practice demand so much apparatus, and such precision in its use, that skilled and judicious surgeons insist upon the removal of their patients to the hospital. Not less important is the hospital for the treatment of a largely increasing number of diseases that fall to the care of the physician, and to the specialist. So impressed are practitioners with the necessity of hospital care of their patients that many are creating their own private hospitals.

We are justified in concluding that there is to be a constantly increasing demand for hospital accommodations for the sick of New York. It is, perhaps, not unwarranted to predict from the experience of the past that the time is not distant when acute diseases will not be treated in the homes of the people, but in hospitals.

(2) **What Shall be the Organized Municipal Authority Having Jurisdiction of the Hospital System Suggested?** There should be created a "Department of Hospitals." The chief officer should be a "Commissioner of Hospitals," who should be a physician of not less than ten years' experience in hospital practice, and of assured executive ability. The "Department of Hospitals" should be under the control of a Board consisting of the Com-

*A paper prepared for the Discussion of the "Hospital Question" before the New York County Medical Association.

missioner of Hospitals, the Commissioner of Charities, and the Commissioner of Health.

This plan of organizing a department is similar to that of the Department of Health, the Board of which consists of the Commissioner of Health, the Commissioner of Police, and the Health Officer of the Port. The object sought to be accomplished is the union, in the government of the Department of Hospitals, of the allied departments which have an interest in its operations. The Department of Hospitals should exercise complete control of all the public hospitals now or hereafter created, viz., the Bellevue and Allied Hospitals, the hospitals under the control of the Department of Charities, and the Contagious Diseases Hospitals under the control of the Department of Health. The assignment of ambulance districts to hospitals should be transferred from the Police Department to the Department of Hospitals.

(3) What Should be the Relation of the Department of Hospitals to Private Hospitals?—The Department should have the duty of approval or disapproval of the certificate of incorporation of all private hospitals, now imposed by statute upon the State Board of Charities, and such approval should be based on the facts required by that Board, viz.: 1. The desirability of such hospital at the time and place proposed in the certificate. 2. The responsible character of the proposed incorporators. 3. The adequate financial resources of the promoters. The Department should utilize the private hospitals in the care and treatment of dependent patients, when satisfactory arrangements can be made with the managers. There are many private hospitals so located, constructed, and equipped that they would form an important part of the hospital system suggested if they were subsidized by the payment of an adequate sum for the care of the patients received by them. Vast sums of money expended in the construction, equipment, and management of new hospitals could be saved if the public authorities would pay private hospitals a liberal *per capita* allowance for the treatment of charity patients. The Department should have visitatorial powers of all private hospitals, and such supervisory jurisdiction as will harmonize their management with the system of hospital administration created by the Department.

(4) What Should be the Relation of the Public Hospitals to the Medical Profession?—Every person who is legally qualified to practise medicine in the State of New York should be allowed to send his patients to the public hospitals of the city, to attend his patients exclusively while in the hospital, and to invite any legally qualified practitioner to cooperate with him in the treatment of his patients, whether as a consultant or operator. This plan of organizing the hospital service has been pursued for many years by hospitals in this State with the happiest results.

The exclusion of the medical profession from a participation in the benefits of a public hospital is not only a wrong to that profession, but works a serious injury to the sick. Under present hospital regulations, the medical staff exercises all the powers of the most exacting monopoly though the method of appointment secures only ordinary practitioners. Physicians, not members of the attending staff, whatever may be their abilities or rank, have no rights in the hospital. On sending their patients to a hospital they lose all control of the care and treatment, which are assumed by the physicians who have been so fortunate as to be appointed to the medical staff of the hospital. The result is that the outside physician loses his patient, and, what is perhaps of more importance, the patient loses his physician. Hence, large numbers of medical practitioners, perhaps more competent to treat their patients than the members of a hospital staff, refuse to send their patients to a hospital, though the disease is of a kind to require hospital advantages for successful treatment. This old-time custom of excluding the profession from the benefits of hospitals has come down to us from the hospitals of London, and ought to be abolished in this progressive age.

(5) What Should be the Relations of the Public Hospitals to the Medical Schools?—Practical instruction in hospitals is becoming more and more recognized by the Medical Colleges as an essential part of a complete medical education. It is good public policy to encourage the promoters of medical education to utilize the hospitals under municipal control for the purpose of clinical instruction by giving them access to the patients under proper rules. The popular prejudice against the admission of medical students to the wards of hospitals for the purpose of bedside instruction was formerly intense. It was regarded as an outrage upon the patients to expose their diseases to the observation of a class of students. In practice, however, it was found that the patients in a ward who were selected for study were very proud of the distinction, while those who were passed by were offended at their apparent neglect. The facts established by experience show that the benefits of clinical instruction are reciprocal as between the hospital and the school. The hospital which has the most perfectly organized system of clinical instruction has the most thorough and exhaustive investigation of the diseases of the patients, and, as a consequence, the highest grade of treatment, and this necessarily results in the most efficient administration of the entire hospital. On the other hand, the value of clinical instruction to the school is inestimable. The time is not distant, we trust, when the hospitals of the city will, as in the European capitals, be the centers of medical instruction, rather than merely accessories.

(6) What Should be the Relation of Public Hospitals to the People?—The public hospitals, built and supported by public funds, should furnish adequate facilities to all classes and conditions of the people, who, by accident or disease, require the advantages of hospital care and treatment. To meet these requirements the hospital should be so constructed as to furnish apartments adapted to every rank and grade of society, from the charity patient to the millionaire. The rate of pay should be scaled on the basis of the accommodations supplied, whether in a general ward, a room with one or more occupants, or an entirely private apartment, or apartments. Moreover, the patient who pays for hospital accommodations should have the privilege of selecting as his medical attendant any legally qualified practitioner, unconnected with the hospital staff, and all the resources of the hospital should be given to the service of such practitioner.

(7) What Should be the Classification of the Public Hospitals Adapted to the Necessities of the People?—The first class of hospitals which the sick and injured require is that which meets emergencies, viz., "The Emergency Hospital"; the second class should provide for the sick during convalescence, viz., "The Convalescent Hospital"; the third class should be equipped for the treatment of special forms of disease, viz., "The Special Hospital"; the fourth class should be devoted to diseases which require isolation, viz., "The Contagious Diseases Hospital."

(8) The Emergency Hospital.—The first hospital in the proposed system is the Emergency Hos-

pital, where the sick and injured receive first treatment. The capacity for these hospitals must vary with conditions, but in general it would be comparatively limited, as the term of residence of those requiring its special care and treatment must necessarily be brief. As much will depend upon the character of the population of the locality it may be estimated that their capacity will be for 300 patients as a minimum, and 600 patients as a maximum. The location of these hospitals must be in the vicinity of the people they are intended to serve. To determine this fact the city should be divided into *Hospital Districts,* the division being based on the laboring or tenement-house population, and registered sickness.

The construction of an Emergency Hospital in New York City admits of a variety of plans and details. The principle governing the construction of hospitals since the Civil War is to the effect that the danger to the health of the people, in domicil, increases in proportion to the increase of the persons occupying a given ground space. Therefore, the wards were spread out over a large area and were one, or at most, two stories in height. This sanitary maxim is true where people live in loosely constructed structures, or in many-storied buildings in which one story ventilates freely into another. In the country where land is cheap and construction work is not of the highest order, the best style of hospital architecture is the cottage form, with wards one or two stories in height. But in a city where land is expensive, and construction is under close governmental supervision, the conditions are so completely changed as to warrant an entire reversal of the ancient sanitary maxim. The modern "apartment hotel" has demonstrated the fact that construction may be so perefct that, in the multiplication of stories in a city structure, the healthfulness of apartments increases in proportion to their distance from the level of the street. The lofty apartment houses are rapidly supplanting the old style residences, on account of both health and the many additional conveniences and economies in living. In like manner the many-story hospital is destined to supplant, in cities, the two or three-story structures. The lower two or three stories will be devoted to the administrative duties, while the higher stories, exposed to the sunlight and free air of the country, will be devoted to the sick.

The plan here suggested of building a series of Emergency Hospitals, ten, fifteen, or more stories in height, on very limited areas of ground, in "Hospital Districts" carefully defined according to the needs of the people, greatly simplifies the problem we are attempting to solve. In the first place it will not be necessary to select expensive plots of ground, but any available place within a given distance could be taken. Next would be the diminished cost of building owing to the compactness of the structure; it is estimated that such buildings could be erected for hospital purposes at a cost per bed not to exceed $1,000. Again, the administration of such a hospital would be far less cumbersome and expensive than the old-time Cottage Hospital. Finally, the healthfulness of the hospital of many stories would be far greater than the hospital whose wards are constantly exposed to the foul air, heat, and noise of the streets.

The Attending Staff should consist of two grades, viz., the Senior and the Junior. The term of service in each grade should be five years, or a total of ten years in both grades. The Senior grade should be filled by promotion from the Junior grade, and no person should be eligible to the Junior grade who is over fifty years of age, nor who holds a similar position in another hospital. The Senior Attending Staff should have supreme control of the division of the service assigned to each, and the Junior Attending Staff should act as assistants and substitutes to the Seniors.

The Resident Staff should consist of two grades of graduates, viz., the Senior and the Junior. The term of service should be six months in each grade, or one year in both grades. The members of the staff should be residents through both terms. In apportioning the service an average of fifty patients should constitute a division to which an individual member of the Senior Attending Staff and his assistant, and a Senior and Junior member of the Resident Staff, is assigned. The service should be continuous.

The Consulting Staff should consist of two classes, viz., (a) General Consultants, and (b) Special Consultants. The General Consultants should be physicians and surgeons who have served the full term of ten years in the hospital, and the Special Consultants should be eminent practitioners in branches of medicine and surgery, classed as specialties. When the Consultants of either class are called in consultation on patients, in public hospitals, they should be paid a reasonable professional fee.

The Medical Board should consist of the Senior Attending Staff, and any member of the Junior Attending Staff acting as a substitute. The Medical Board should be responsible to the Department of Hospitals for the nomination of all subordinate officers and for a close, daily supervision of the order, discipline, efficiency, and economy of every branch of the service.

The Executive Officer should, preferably, be a physician of assured executive efficiency. The Executive Officer and subordinate officials should be recommended by the Medical Board to the Department for appointment, and no such official should be appointed without such recommendation.

The special features of the above plan of organizing the Medical Service of an Emergency Hospital, which require comment, are as follows:

1. The division of the Attending Staff into two grades, Senior and Junior, is important, viz.: (a) The diseases of the patients being acute, the members of the staff should visit daily, which requires that there should be two attendants to meet emergencies. (b) The training of the Junior member, during his five years' service, fits him to take the place of the Senior, on retirement, and thus a high degree of qualification is maintained in the medical service. (c) A fixed term of service of ten years, five years in each grade, is ample in an Emergency Hospital, to secure all the benefits of experience that a hospital can confer: if the term is limited the attendant is far more likely to attend strictly to his duties in order to gain all the advantages possible during his term; within ten years a competent physician will secure a private practice which will absorb all his interests and energies; finally, the limited term admits of the admission of a far larger number of capable and deserving young physicians to the advantages of hospital practice. This scheme would result in a reform of the present obsolete practice of appointing men for life to hospital staffs, many of whom, far advanced in years, hold similar positions in other hospitals, and would give scores of competent graduates opportunities for hospital experience. (d) Hospital consultations are too much neglected. Every medical staff of a hospital should have the counsel and advice of men of large experience when emergencies occur in practice, and hence the necessity of the two grades of Consult-

ants. The General Consultants are men who have already served in the hospital for a full term of years, and are able to appreciate the conditions which are present, and which require a judgment based on experience for their proper determination. The Special Consultants are necessary to meet satisfactorily the emergencies which arise on the admission of special forms of disease. The professional fee is the just due of the Consultant of either class. (e) The term of one-year service for the Resident Staff, in two grades of six months each, would secure greater devotion to duty and admit a larger number of recent graduates to the advantages of the hospital. (f) The continuous service and an average of fifty patients to each division secures that continuity of treatment of, and interest in, individual patients, so essential to their recovery. (g) The Medical Board should be composed of officers having the largest experience in the affairs of the hospital, and immediately responsible for every detail in its management.

(9) Convalescent Hospitals.—The questions which arise in the discussion of the establishment of Convalescent Hospitals are much more readily determined. The most important are, (a) Location; (b) Construction; (c) Administration.

(a) The location of a Convalescent Hospital should be in the open country, on an elevated site, easily accessible to the city. The location should be on a water front navigable from the city, for two reasons, viz.: 1. For facility of transportation of both passengers and supplies, and, 2. For the curative effect of the recreation afforded to the sick by excursions on the water. The site should contain ample grounds for the cultivation of farm supplies, as vegetables, milk, fruits, stock. There is a great variety of available sites for Convalescent Hospitals along the shores of the Bay, the Sound, and Hudson River, within suitable distance of the city.

(b) The Construction should be a colony, with cottages of the family type, and sufficient in number to allow of minute classification. These structures should be very simple and inexpensive, but substantial and durable. It has been experimentally determined in Germany that convalescents who do suitable work out-of-doors, on farms, recover much more rapidly than do those confined in city hospitals.

(c) The administration of the Convalescent Hospital should be under the direction of a medical officer of large experience in the practical duties of hospital management, with a resident medical staff of recent graduates, having a limited tenure of service. The Training School for Nurses of the Department should be located in this hospital, and, by properly arranged scheme of assignment, should furnish nurses to all of the other hospitals. The members of the attending staffs of the various hospitals should have the right to the continuous care of the patients whom they send to the Convalescent Hospital.

(10) Special Hospitals.—There is a growing need of well-equipped and managed special hospitals in this city in which instruments of precision are necessary to successful treatment. The provisions made in existing hospitals and dispensaries for the treatment of the special diseases of the poor, as of the eye, ear, nose, and other organs, are inadequate and preventive of that high grade of success. The importance of these special institutions is seen in the crowds which throng the few better-conducted hospitals and dispensaries, numbering often five and six hundred during the two or three hours of attendance. The proper treatment of the diseases of sensitive organs, as the eye and ear, requiring the expert use of delicate instruments, under these conditions of rush and confusion, is impossible. The only possible relief to those seeking treatment of special diseases is a large increase in the number of thoroughly equipped hospitals and dispensaries devoted to these specialties.

(11) Contagious Diseases Hospitals.—These hospitals were formerly under the control and management of the Department of Charities. Owing to their inefficiency, the Department of Health, in 1872-3, began to create hospitals for contagious diseases on an entirely new basis of location, construction, and management. The value of these new hospitals was at once demonstrated. The protection which they have afforded the tenement-house classes from the brood of domestic pestilences which formerly decimated the homes of the poor cannot be estimated. The remarkable improvement in the efficiency of these hospitals when removed from a department devoted to the custodial care of the poor to a department having expert knowledge of contagious diseases, strikingly illustrates the defects of our hydra-headed system of hospitals.

(12) Organization of Hospital System.—The practical application of the foregoing suggestions to existing conditions could be much more readily effected if the previous development and growth of our hospitals had been along definite and well-devised lines, and under a competent municipal authority. But even in their present chaotic state as regards location, construction, and division of authority in management, a serious effort should be made to so organize them into a system that during the present century they will develop symmetrically, and thus be better adapted to fulfill their mission to the sick efficiently and economically. To that end the following suggestions as to the method of organizing the hospital system, above outlined, are submitted:

1. The "Department of Hospitals" should be provided for by an amendment of the charter of the city.

2. When organized the Department should create "Hospital Districts," the division of territory being based on the population of the laboring or tenement-house classes and the sickness-rate.

3. The following public hopitals should become "Emergency Hospitals," with properly assigned districts, viz., Gouverneur, Bellevue, Harlem, Fordham. In furtherance of this plan, the proposed New Bellevue Hospital, to accommodate 2,000 or 3,000 patients and to be built at a cost of upwards of $12,000,000, should be discarded, and an Emergency Hospital should be constructed there on the plans above given, to accommodate 600 patients. The remaining grounds should be sold, the income of which would construct the proposed Bellevue Emergency Hospital and provide a Convalescent Hospital. This plan would save to the city, not only the $12,000,000 for the greater Bellevue, but, as seen in paragraph (5), also the $7,000,000 for the extension of hospital accommodations on Blackwell's Island.

4. In providing Emergency Hospitals for districts where none now exist, the Department of Hospitals should endeavor, first, to arrange with any private, well-equipped hospital in that vicinity, by suitable payment for the care of public patients, to become the "Emergency Hospital" of that district. There are a large number of private hospitals which would gladly accept that position and thoroughly perform its duties, if they could be com-

pensated adequately, thus saving to the city the enormous cost of erecting, equipping, and managing its own hospitals.

5. One or more "Convalescent Hospitals" should be at once created on ample farm lands located on the water front within easy access of the city. When such a hospital is ready for occupation the inmates of the hospitals on Blackwell's Island should be removed as they convalesce to the "Convalescent Hospital," and these Island hospitals should be converted into infirmaries for the incurables and other classes in that Department of Charities. By this change the $7,000,000 required for the additions to these buildings for hospital purposes would be saved to the city, and the accommodations of the Department of Charities would be greatly improved.

6. The "Special" and "Contagious Diseases" Hospitals would take their proper places in the system of hospitals organized by the proposed Department of Hospitals, and their location, organization, and management would be in accordance with the latest teachings of science and experience.

300 Central Park West.

REPORT OF TWO CASES OF DEMENTIA PARALYTICA, ONE ASSOCIATED WITH A LARGE HEMORRHAGIC LESION, THE OTHER WITH ATROPHY OF THE OPTIC TRACT.

By JESSIE WESTON FISHER, M.D.,

MIDDLETOWN, CONN.

FROM THE LABORATORY OF THE CONN. HOSPITAL FOR THE INSANE.

Though medical literature abounds in discussions of dementia paralytica in all its phases, few cases are recorded associated with gross focal lesions of the brain.*

Case I.—A. C., a well-developed male probably forty-eight or fifty years old, was arrested by the police for disorderly conduct and intoxication about two weeks prior to his admission to the Connecticut Hospital for the Insane, but subsequently it was ascertained that he was insane. No information was obtained in regard to his family or personal history, or the psychosis up to the time of his arrest. Upon admission to the hospital, and during residence there, he presented symptoms of the expansive form of dementia paralytica, accompanied by considerable deterioration. His memory was markedly impaired. His train of thought was desultory and he talked incoherently, never reaching a goal idea, and presenting many rapidly changing delusions of grandeur. His emotional state was one of elation in accord with his expansive delusions. He sat around the ward happy and contented, singing softly to himself, absolutely oblivious of his environment, or of his personal needs.

Physically, there were marked ataxia, Romberg's symptom, tremor of tongue, eyelids and facial muscles, exaggerated patellar reflexes, faulty articulation, and equally contracted pupils, which responded sluggishly to light and accommodation. At the end of a year he was more markedly deteriorated mentally, the patellar and deep reflexes were apparently abolished, the pupils were equally contracted but irresponsive to light or accommodation, and he was unable to stand alone. He laughed and sang happily the greater part of the night, but was generally quiet and stupid during the day. He deteriorated rapidly in the next few months, and ground his teeth together hours at a time until they were worn down to the gums, causing much laceration and swelling. From this time on he would lie in bed, softly crooning to himself, unmindful of his personal needs or of his environment.

Fig. 1.—Case I. *a*. Indicates the anterior tip of the lesion in the left side.

About one year before his death there was observed a progressive paresis of the muscles of the right forearm, accompanied by increasing contractures. This gradually extended to the upper arm, to the left arm, and both legs, so that at the time of death, three and a half years after admission to the hospital, the arms were strongly adducted with flexed forearms, while the legs were firmly flexed upon thighs, and thighs upon the abdomen.

An autopsy was performed some fifteen hours after death. The brain weighed 1,115 grams, and presented general cerebral atrophy, chronic lepto-

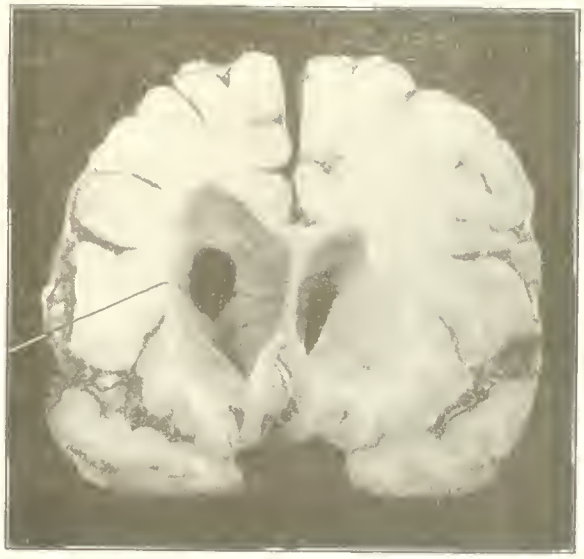

Fig. 2.—Case I. *a*. Note the marked dilatation of the left ventricles and the reduction of the caudate nucleus.

meningitis, and edema of pia. The left hemisphere of the cerebrum was slightly reduced in bulk, with a corresponding reduction of the right cerebellum. The frontal lobes were adherent. The cord presented calcareous placques in the pia. Frontal section of cerebrum revealed marked dilatation of the anterior horn and body of the left lateral ventricle. The posterior horn of the left, the entire right, and the third ventricles were moderately distended, and the ependyma of all presented marked granulations.

*The two cases here reported were on the service of Dr. A. B. Coleburn, to whom we are indebted for valuable notes. I wish also to express my grateful appreciation to Dr. A. R. Diefendorf for report of autopsy and suggestions.

The corona radiata of the left hemisphere presented an area of hemorrhagic degeneration measuring in frontal section anteriorly 4 cm. by 1 cm., and about 6 cm. by ½ cm. at the broadest portion. It began just anterior to the tip of the anterior horn of left ventricle, extending posteriorly to the dorsal extremity of the caudate nucleus. It was located above, below and external to the ventricle, forming almost a half circle around it. The caudate nucleus was much reduced in size, especially in the middle third, where it was so attenuated as to be scarcely recognizable. The lesion was grayish in color, and very spongy. Microscopically, it was composed of vacuoles surrounded by a compact mass of fine fibrils, with an increase of neuroglia cells. It lay in apposition to a similar, though much smaller lesion, involving the cortex, as well as some subcortical tissue of the external portion of the gyrus rectus. The structures involved in the larger lesion were the left caudate nucleus, the corona, lying adjacent to the external wall of the anterior horn and body of the lateral ventricle, as well as the anterior limb of the internal capsule.

FIG. 3.—Case I. *a*. Shows the lesion almost encircling the lateral ventricle, which is markedly dilated. Also note dilatation of right and third ventricles.

Microscopical examination of the cerebral cortex showed the characteristic vascular changes of dementia paralytica. The right and left paracentral regions were studied, but the most marked changes were observed in the right and left first frontal convolutions. The cortex was everywhere atrophied, many cells having fallen out, while the others were crowded irregularly together. Neuroglia cells were generally shrunken and deeply stained, but not increased in number. The blood-vessels were increased in number, showing periarteritis, with infiltration of the adventitia by small, round cells, plasma cells, and mast cells. Stäbchenzellen (red cells) were numerous in the vicinity of vessels. The contour of the small nerve cells was irregular, very few processes being traceable. The chromatic substance presented a fine network of partially-stained fibers. The nucleus was not always centrally placed, and was often distorted and deeply stained with nucleolus frequently seen at the periphery. There was marked central chromatolysis of the Betz cells, with staining of the achromatic substance, accompanied by a pigmentary deposit at base of cell and vacuolation of nucleus.

The spinal cord presented arteriosclerosis, with marked degeneration of fibers of the right-crossed pyramidal tract, with moderate degree of degeneration in the left direct pyramidal tract, and in the column of Goll on both sides.

CASE II.—J. W. This patient was a well-developed, temperate Irish laborer. Syphilis was denied, and family and personal history were negative up to his thirty-eighth year, when he suddenly lost the sight of both eyes, about which occurrence nothing more definite could be learned. There was no mental change noted for seven years after the loss of vision. At this time he had a "shock," which was said to have affected his hands and speech. He was mute for about an hour, after which his speech was stuttering in character. His insanity came on gradually following this "shock," and was characterized by insomnia, defective memory, irritability, talkativeness, excitability, and violence.

He was admitted to the Connecticut Hospital for the Insane, September 26, 1902, nearly eight months after the so-called "shock," and over seven years after the loss of vision. At the time of admission he was totally blind, except for the distinction between light and darkness. No hallucinations were elicited, but he was completely disoriented. His memory was seriously impaired, his thought was apparently very limited, and his replies were irrelevant and incoherent. No delusions were elicited during his residence in the hospital. Emotionally, he showed slight oscillations with predominance of depression, but volitionally he manifested no marked change.

Physically, he presented almost complete blindness, shuffling gait, Romberg's symptom, stuttering, explosive, and indistinct speech, tremor of eyelids, tongue, and fingers, active superficial reflexes, a moderate Babinski sign, and active patellar reflexes. He continued in much the same condition for a couple of months, when he became very restless, and frequently groaned as if in pain, but when questioned denied any uncomfortable sensations. His intellect was markedly deteriorated, and he showed considerable physical impairment, with incoordination, especially of the leg muscles.

Five months later the patient gave evidence of extreme pain by groaning, moaning, and moving restlessly from side to side. The next morning he was found in a semicomatose condition, with hands, arms, and legs twitching continually, and eyes turned to the left side. The muscular twitching subsided during the day, but he never regained consciousness, dying at 6 P.M. February 27, 1903, about one year after the so-called shock.

FIG. 4.—Case I. *a*. Note the reduction in size of the lesions and the reappearance of the caudate nucleus.

The autopsy was performed five hours after

death. Aorta and coronaries were sclerotic. About 3 cm. above the aortic valve there was adherent to the atheromatous vessel wall, a globular thrombus 2.5 cm. in diameter, which nearly occluded the lumen of the vessel. The thrombus was composed of a mixed clot, elsewhere the aorta, while atheromatous, was free of clots, but the mesenteric artery about 3 cm. from its origin contained a thrombus about 3 cm. long, firmly adherent to the vessel wall, with beginning necrosis of intestine.

The dura was free, but the frontal lobes were adherent. The pia was everywhere thickened, more especially over the motor, frontal, and temporal regions. The same areas showed shrinkage of the convolutions. The vessels at the base were sclerotic, but there was no external evidences of cerebral hemorrhage or embolism. The brain weighed 1.437 grams. The floor of the fourth ventricle was slightly granular. Frontal section was made one month after autopsy, when slight dilatation, with marked granulation of ventricles, was found. There was atrophy of both optic nerves and tracts, and the lateral geniculate bodies of each side were about one half normal size. These were brownish green

FIG. 5.—Case I. *a*. Showing only the extreme posterior tip of the lesion. The dilatation of the posterior horns of the lateral ventricle is nearly identical.

in color, and the white laminæ were completely absent. The superior corporaquadrigemina were somewhat reduced in size, and the superior colliculi were entirely absent.

Microscopically the right paracentral lobule (stained by Nissl's original method), showed the pia thickened and infiltrated with small, round cells. Immediately beneath the pia a few corpora amylacea were seen. The vessels were increased in number, their walls being much thickened, and the adventitia infiltrated with small round and plasma cells with much pigmentation. Stäbchenzellen (rod cells) were numerous in vicinity of vessels. The neuroglia cells were not increased in number, but their nuclei were shrunken. The neuroglia fibers were increased in the first layer. The regular arrangement of nerve cells was lost, and they were crowded together, the intercellular substance being much reduced. The small nerve cells were normal in shape, but somewhat irregular in contour from retraction between the processes, which were traceable but a short distance. The cytoplasm was composed of a fine, irregular reticulum of slightly stained fibers with many vacuoles. The nucleus was shrunken, deeply stained, and often triangular. The nucleolus was frequently seen at the periphery of the nucleus and was very deeply stained. The Betz cells were shrunken, the contour irregular from retraction, and the processes were not traceable. The chromatic substance exhibited no granules, except near the apical process. The achromatic substance was stained, giving a homogeneous appearance to the cell. The nucleus was shrunken, elongated, deeply stained, and the membrane thickened. The nuclear cap was very prominent and the nucleolus deeply stained.

Frontal section, as well as the left paracentral lobule, showed an increase in the number of neuroglia cells, the presence of many satellite cells, and the "rassen" formation of Nissl; otherwise the sections closely resembled those of the right hemisphere. In the cord there was a degeneration of a large number of fibers in the crossed pyramidal tract of the right side, the cervical and lumbar regions suffering the most.

In the first case there were no unusual symptoms until about one year previous to death, when contractures of the right side were noted, beginning with the hand, but gradually involving the arms and legs of both sides. The absence in this case of any history of shock, or any symptoms pointing towards a focal lesion, leave us in the dark as to the primary affection. Whether the hemorrhage antedated the mental symptoms, or appeared during the psychosis and was masked by it, is impossible to say.

In the second case, however, the sudden blindness, "shock," and dementia rather masked the symptoms of general paresis, so that there was some doubt as to the diagnosis before autopsy.

The duration of the disease does not seem to have been affected by the focal lesion, nor did it color the picture to any great extent in the first case.

THE INTESTINAL BACTERIA; HOW THEY ACQUIRE TOXICITY, AND HOW TO DETERMINE THIS EXPERIMENTALLY FOR CLINICAL PURPOSES.

BY E. PALIER, M.D.,

NEW YORK.

IN spite of the fact that a great deal has been written on the common intestinal bacteria, we are practically not much the wiser. We know that ordinarily the intestines contain numerous microbes, which may become harmful to the system, but the question is whether the same microbes of the intestines which are ordinarily harmless may become injurious, and if so under what conditions; or whether they cannot, and the harmful microbes are newcomers and are derived from other sources.

This most important question has not been answered clearly and definitely, but vaguely and guessingly. We often hear such explanations as lowered resistance or vitality, which are simply empty phrases, as we are not told in what the low resistance consists, how it is brought about, or how to prevent it. Such phrases make matters still more obscure, and those who do not wish to deceive themselves or their fellow men by using words without meaning, had better not use them at all. In this paper the writer will attempt to answer this question clearly from experimental facts.

First, however, it is necessary to know what bacteria are usually found in the intestines of man. An exhaustive treatise on this subject is given by Prof. Mannaberg.[1] It would be unprofitable to discuss here at length a subject that has been already so ably discussed.

A great many microbic species are said by inves-

tigators to have been isolated from the intestines, *i. e.*, the feces, as the bacteria are usually studied from the feces, and it is assumed that naturally they represent those of the intestines. This is so if proper precaution is taken to prevent the contamination of the feces by the bacteria from the container, the air, etc. In all probability some of the discrepancies in the findings of some authors are due to such contaminations.

The following bacilli are said by investigators to have been found in the intestines, *i. e.*, feces of man: (*a*) *Bacillus coli* or some of its congeners, like the *B. lactis ærogenes;* (*b*) *B. subtilis;* (*c*) *B. mesentericus vulgaris;* (*a*) *B. butyricus.* and (*c*) some other species. All investigators agree that the coli bacilli are constantly found in the intestines of man, even in those of young infants, and they have been found even in the meconium of newly born infants. It is a polymorphous organism, and according to Mannaberg the same microbe has been rediscovered under different names, with which I fully agree. I shall revert to it soon again. The other bacilli mentioned above are admitted not to be constant hosts of the intestines, but are found now and then. Anaerobes are, of course, found now and then; but the statement made by some that they are constant hosts of the large intestines is not true.

As to cocci, investigators agree that in one form or another they are also constantly found in the feces.

I have made a number of examinations of the bacteria of the feces, and in some cases the gastric contents of the same individuals were also examined chemically and bacteriologically. In cases where the gastric juice was normal, or in hyperchlorhydria, the only microbes I found in the feces in cultures were the coli bacilli and cocci, and in some cases of hyperchlorhydria an organism resembling the *Oidium lactis*, but which took the Gram stain, and fungi were also found, but none of the other bacilli mentioned before claimed to have been found by other authors. Several examinations of the feces of the same individuals at intervals gave nearly the same results. The authors, who claim to have made investigations of the intestinal bacteria, fail to state whether or not they examined the stomach contents of the same individuals.*

I have treated elsewhere of the bacteria which are likely to be found in the various conditions of the stomach, and it would be unprofitable to dwell on this subject here. Some investigators seem, however, either to be unaware of these findings or to neglect them entirely. I wish, therefore, to repeat here briefly and emphatically, that in a normal human stomach after a light meal, the only bacteria that can be found is yeast, and in hyperchlorhydria, especially when accompanied with alimentary stasis, there may be found in addition a small bacillus named by the writer, the bacillus chlorhydrici, and also sarcinæ, and sometimes fungi.[2] But no other bacilli are found as a rule in such conditions of the stomach.† In achlorhydria, where the gastric juice exerts little or no germicidal powers, other microbes can be found in the stomach, and the bacterial flora in the intestines are also apt to be richer, and in some cases they are.

It must be stated emphatically that many microbic species are never found at the same time in one natural medium. The writer has carefully examined the sputum, the gastric juice, and the feces, and he states positively that very seldom are more than four species of microorganisms found at one time in any of those natural media, and most frequently there are only two or three. It stands to reason that many species cannot grow together in the same medium, as the slowly growing ones are necessarily destroyed by the fast-growing. This is a well-known biologic law, and we see it all over in nature.

The coli bacilli and the cocci which are found in the intestines of individuals whose stomachs are normal, or in a state of hyperchlorhydria are probably old inhabitants, having found their way perhaps soon after birth, before the gastric secretion was fully established. For, though repeated examinations of the stomach contents did not show any such microbes, yet they were found in the feces of the same individuals. In the feces of a suckling infant ten weeks old, examined by the author at that age, and a month later, each time only coli bacilli and the same cocci were found. There were no other bacteria at the second and third examinations; evidently the stomach of the infant does not allow the passage of new bacteria. This may happen, however, under certain conditions, when the stomach is overtaxed or otherwise greatly disturbed. But it would appear that such an occurrence is the exception rather than the rule.

But as for the feces, admitting even that besides coli bacilli and cocci there may be found now and then some of the microbes referred to above, such as *B. subtilitis*, *B. mesentericus vulgaris*, etc., as they are nonpathogenic, their presence is practically of no importance. We thus have to deal with only two microorganisms which are constantly found in the feces, and which may become pathogenic, and these we shall consider here.

We shall first take up the coli bacilli. The morphology and cultural peculiarities of this microbe have been sufficiently described in standard works, so they need not be treated here. But as to the virulence the status of the colon bacillus has not been clearly established. We know that it is sometimes virulent and sometimes it is not. Thus, according to Lesage and Macaigne,[3] the microbe in question is nonvirulent when taken from healthy intestines, but when the intestines are affected, when there is diarrhea it is found to be virulent. The question to be decided is whether the nonvirulent colon bacillus may become virulent, and if so under what conditions; or whether the virulent and the nonvirulent coli bacilli are two different microbes, derived from different sources. Furthermore, it has not been proven to us whether the virulent coli bacilli found in diarrhea, as stated by Lesage and Macaigne, are the cause of the diarrhea or the effect of it. This question will be answered from the following facts:

In studying the feces of mice and rats the writer has always found in them cocci and coli-bacilli, or some of their congeners. The same microbes were also found in the intestines and in the stomach of these animals. It has been said in the stomach, which is not the case with normal stomachs of human beings. The stomachs of mice and rats contain hardly any hydrochloric acid, as was shown repeatedly by applying the usual tests for HCl; therefore, the above-mentioned microbes can be found in it, whereas they cannot thrive in a stomach containing a normal amount of HCl.

Now, by injecting into mice intraperitoneally fresh agar cultures of coli bacilli and cocci obtained from the feces of mice fed on bread and water, there

*Some authors describe microbes which they did not isolate in cultures, but which they claim to have seen in smear preparations. This is, of course, ridiculous, as one can never identify microbes except in cultures.

† An investigator recently claimed that ulcer of the stomach is caused by the coli bacilli. If that investigator had examined conscientiously the human stomach he would not have made such an absurd claim, as in ulcus ventriculi there is usually hyperchlorhydria.

was no effect at all. Some time ago, however, the writer isolated coli bacilli from a dead mouse, and, by injecting into mice intraperitoneally small doses of such an old agar culture, the mice thus injected invariably died within twelve hours. A fresh culture was then made from the three-months-old one, and the fresh one, when it was only two days old, was injected into mice, and, to the writer's surprise, the new culture did not act as did the old one. Of five mice injected, three died in about eighteen hours, on one there was no effect at all, and one died in four weeks.

It is interesting to say a few words concerning the last animal. There is, as a rule, an inflammatory state of the peritoneum and intestines of animals dying from the injection of virulent coli bacilli. The last-mentioned mouse was unwell all the four weeks, as was evidenced from its apathy and its apparent weakness in the hind legs. After its death its abdomen was greatly distended, and on dissection the intestines and stomach were greatly distended with gas, and were very thin, appearing like big soap bubbles; but there was also an inflammation of the peritoneum, the intestines, and the stomach, and the bubbles were greenish, and in spots reddish. The same condition may occur in human beings in chronic affections due to the coli bacilli.

Coli bacilli are, as a rule, found in the blood of dead mice, and also in other animals, some hours after their death, no matter what the cause of death may be. Frequently there are also found in the blood of dead mice cocci, which have been dealt with by the writer elsewhere.[1] Now, the coli bacilli from dead mice have always shown a great virulence. They evidently enter into the blood of the dead animals from the alimentary canal, and not from the air, because frequently they are the only bacilli present, no other bacilli usually found in the air being present, except, of course, when decomposition has already fully set in.

The same microbe, then, which is nonvirulent when obtained in cultures from the feces of a healthy animal fed on bread and water only, is virulent when obtained from the blood of the same animal when dead.

It is frequently stated that during life certain antibodies serve to mitigate or to diminish the virulence of bacteria. How far this is correct in general it would be out of place to discuss here. But it certainly cannot explain why the coli bacilli obtained in cultures from feces of mice fed on bread are nonvirulent, as the feces are just as much dead matter as the dead body of the mouse, and the former can no more form antibodies than the latter. The explanation we shall see immediately. It has been referred above to the feces of a healthy suckling infant studied by the writer. The feces, as has been said, contained coli bacilli and cocci. The former differed slightly morphologically from those found in dead mice, in that they were bigger; otherwise they were alike. The cocci were diplococci, and some of them formed short chains of from four to eight individuals, resembling short streptococci. Now, on injecting intraperitoneally into mice two days old agar cultures containing both the coli bacilli and the cocci, obtained from the feces of the infant in question, no effect was produced. The same was repeated at an interval of a month with fresh cultures, from fresh feces, with the same results. The idea suggested itself to me that the nonvirulence of the coli bacilli obtained from the feces of mice and from that of a suckling infant was due to the fact that such feces are deficient as a nutritive medium, and that the coli bacilli, in order to attain virulence, must have a medium of dead flesh.

To test the matter, the following experiment was made: A piece of butcher's meat was boiled for about half an hour; then it was put into a test tube, and to this was added normal gastric juice, and left for a few hours. This was done to destroy the bacteria of the meat and to imitate what takes place in the stomach. Before the meat was fully digested the gastric juice was poured off and sterile water added. Then were added a few loopfuls of a fresh culture from the feces of the infant, which culture contained coli bacilli and cocci, and were nonvirulent. At the end of three days an agar culture was made from the test tube containing the meat and sterile water, to which bacteria from the infant's feces had been added. This new agar culture contained again coli bacilli and cocci, and these were injected into mice, and it caused their death in sixteen hours. The same mice which had not been affected when injected with a culture obtained from the feces of the infant (which we shall call culture 1) died when injected with a culture obtained from the test tube of meat, and the latter culture was an offspring of the culture 1. Evidently a nutritive medium of flesh enables the coli bacilli to acquire virulence.

Furthermore, when culture 1 was two weeks old it was tested again, and this time it was found to have an effect on a mouse, causing its death in twenty hours. Indeed, gelose is practically also dead flesh, but evidently it takes some time for the virulence of the coli bacilli to develop in this medium, but it is accomplished much quicker in the body of a dead animal.

From the above facts and from others, which will be referred to soon, the writer considers it justifiable to draw the following conclusions: That a flesh medium enhances the virulence of the coli bacilli, and that in agar, older cultures are, on the whole, more virulent than fresh ones. This latter statement is not in accord with what we know about some other microbes, particularly diplococci and streptococci, which behave differently, nor is it in accord with the statements found in some books, that fresh two-days-old cultures are more active; but such were the findings of the writer, and so he records them.

I have also studied the feces of adults, and will briefly describe three cases.

Case 1. was that of a man of 50, who suffered from gastrointestinal trouble. He had vomiting and diarrhea a few months previous to his coming under the writer's observation, but he improved under treatment. When the writer saw him he had no more vomiting, but he had from three to five evacuations from the bowels daily. The patient was emaciated, had little appetite, and what troubled him most was flatulence. Gaseous distention of the intestines appeared in circumscribed places, simulating a phantom tumor, but there was no real tumor. An examination of the stomach and its contents showed some atony accompanied with hyperchlorhydria and hypersecretion. A bacteriological examination showed yeast and the bacillus chlorhydrici and also some sarcinæ and fungi, but no other bacteria. The feces were semisolid, very offensive in odor, and contained numerous gas bubbles. The feces rose in the container like fermenting dough. Microscopical examination of the feces showed nothing of special importance. Bacteriological examination yielded in cultures coli bacilli and cocci. A six-weeks-old agar culture of this feces injected into a mouse caused its death in twelve hours. Then the coli bacilli were isolated from the cocci and a two-days-old agar culture of the former injected into a mouse caused its death in twenty hours. This was evidently a case of enteritis due to the colon bacillus. What is impor-

tant to note in this case is that the stomach contents did not contain any coli bacilli nor cocci, though they were examined several times very carefully.

Case II. was that of a man of 40 suffering from chronic duodenal catarrh, with flatulence, and a tendency to diarrhea. There is occasional hyperacidity of the stomach, but the motility of this organ is good. Cultures from the feces yielded coli bacilli, cocci, an organism resembling the oidium lactis, but which was Gram positive, and also fungi. An injection of the same into a mouse caused its death in twenty hours, and in the blood of the mouse were found only coli bacilli.

Case III. was that of a woman 35 years old, apparently in good health, with rather costive bowels. This woman had typhoid fever at the age of 16 years, from which she fully recovered, and has been apparently in good health since. She is a heavy meat eater. The feces have a very disagreeable odor. An agar culture therefrom yielded coli bacilli and cocci, which caused the death of a mouse in twenty-four hours.

Cases I. and II. are also meat eaters. Now, from what has been said above, it appears that under a meat diet the coli bacilli of the intestines are most likely to become virulent. This is especially the case when some of the ingested meat happens to pass through the stomach and duodenum indigested so that it affords a good nutritive medium to the coli bacilli. Once the coli bacilli become virulent, they will, in their turn, cause injury to the intestines, and so the pathological process will go on. Under a milk or a vegetable diet some injury may also occur to the intestines from the ingestion of too much food or too irritating food, and the nonvirulent coli bacilli may thus settle at the injured part, thrive there as on dead flesh, and thus continue the pathological process.

I was able to produce sloughing experimentally in this way. The tails of mice were squeezed with forceps and allowed to drag in their own feces in the jar. The tails began to slough away, and the bacteria found on the sloughing tails were those of the feces, *i. e.*, the coli bacilli and cocci. If a clean bed is given to an animal the sloughing discontinues and the tail heals. Thus the injured tail affords a nidus and also nourishment for the coli bacilli of the feces, and endows them with some virulence, as they are not virulent when injected into the very same animals intraperitoneally. But healthy tails of mice, allowed to drag in their own feces, are not affected. Thus, in diseases of the intestinal canal due to the coli bacilli, these bacilli need not necessarily be new intruders, but the old, innocent bacilli may under indiscretion in diet become virulent and pathogenic. Indeed, it has been said that meat eaters are more subject to appendicitis than vegetarians. I quote the following: "Freedom from Appendicitis.—Dr. Nicholas Senn has made an interesting observation while visiting the hospitals in towns on the east coast of Africa. The physicians in those institutions informed him that they had never seen a case of appendicitis among the blacks. . . . . The relaxing effect of climate, laziness, and a fruit and vegetable diet would seem to offer the best explanation of this immunity."[5] How far climate and laziness can have any effect on the intestinal bacilli the writer cannot say, but the effect of diet was shown above.

According to some investigators quoted by Nothnagel (*Erkrankungen des Darms und des Peritoneum*, p. 682) most of the cases of appendicitis are due to the coli bacilli. The same can be said of the affections of the biliary ducts. If we examine the feces of animals living on a vegetable diet, like those of mice fed on bread only, and of cows and horses, and of healthy nursing infants, it will be noticed that there is hardly the offensive odor of the feces of the carnivora like cats and dogs, and of adults partaking of meat, though coli bacilli are found in the feces of all those mentioned. It is because indol, skatol and phenol are not formed in the healthy intestines on a milk diet and a vegetable diet, to any appreciable extent, as they are on a meat diet. The poisonous products of the coli bacilli are evidently less on a diet of the former than on the latter.

The above is said, not with the view of condemning a meat diet entirely, but to show that as far as the coli bacilli are concerned, their virulence is apt to be enhanced by such a diet. How other pathogenic bacteria are affected by it is a question yet to be answered.

Virulent coli bacilli also contain an extra cellular toxin, which they secrete into the medium in which they develop, and hence there may be an autointoxication derived from the intestinal canal.

I shall now say a few words concerning the cocci. A great many varieties of these are said to have been isolated from the feces. As the writer found them, they were usually like those in the feces of the suckling infant mentioned above. They appear usually in the form of diplococci, or form short chains. Sometimes they appear as staphylococci, and in this form they are usually found in the feces of mice. Pageand[6] doubts whether they can cause disease at all, as he found them in the feces of healthy suckling infants, and they were not virulent to mice. That is exactly my experience. Furthermore, whereas the coli bacilli, as was stated before, acquired virulence by passing through meat, the cocci did not. By injecting such cocci alone into a susceptible animal, like a mouse, the animal is not affected. If we inject such nonvirulent cocci, together with virulent coli bacilli, the animal dies, but neither in smear preparation nor in cultures from the blood of the dead animal can cocci be found. In such cases only coli bacilli are found. If, however, we inject both virulent diplococci and coli bacilli, both of these microbes can be recovered in cultures from the blood of the dead animal. When such microorganisms are injected into a mouse intraperitoneally, the animal usually dies in eight hours, and frequently the cocci cannot be seen in smear preparations, but they can be recovered in cultures from the blood of the dead animal.

The cocci obtained from the feces of the other cases seem also to be devoid of virulence.

Thus there seems to be a difference between the cocci obtained from the human sputum and those obtained from the feces. In the former they are, as a rule, somewhat virulent, which virulence can be enhanced by their passage through a susceptible animal like the mouse; but in the latter they seem to have lost their virulence entirely, and it cannot be restored. As to the coli bacilli the case seems to be reversed; they are more frequently found in a virulent form in the feces than in the sputum.

Though it is generally admitted that the coli bacilli are in most cases responsible for appendicitis, yet in some cases cocci, mostly diplococci and streptococci, are found alone in this affection. In such cases the trend of opinion is that the virulent cocci gain entrance through the blood and not from the intestines, and the writer is also inclined to this belief. Furthermore, the affection in question sometimes occurs endemically. Thus Galubow[7] reported an epidemic of appendicitis in Moscow in the spring of 1806; Louenburg, in the spring of 1899 in a certain section of Berlin, and similar reports are made by others. It is noteworthy, however, that these reported epidemics occurred in the spring and winter

months, when pneumonia is most prevalent, and not in months when gastrointestinal diseases are prevalent. The writer has elsewhere brought proofs to show that mice which are very susceptible to the pneumonia bacilli are responsible for this affection. Mice, in fact, are very susceptible to all kinds of cocci, and also to *B. coli*, which latter are enhanced in virulence on passing through the mice. The writer has furthermore proven that these animals are more abundant in houses at certain seasons, and that by their decomposing bodies after their death, or through their feces when they are sick, they are apt to spread very virulent germs. Are not mice the cause also of the local outbreaks of appendicitis, and in fact of most, if not of all, virulent cocci infection? This question is of sufficient importance to be taken up by investigators and to be decided one way or another.

I shall now say a few words concerning the method of testing the virulence of the intestinal bacteria: Obtain some feces, for obvious reasons better at the end of defecation, in a sterile container. Then make two cultures, one in glucosed agar by stab and one on agar slant by smear, and put them into the incubator at 38° C. for forty-eight hours. In hot summer weather the room temperature is sufficient. Make smear preparations of the cultures and stain by Gram and a counter stain like eosine. By examining the cultures and the smear preparations therefrom, one can usually see what bacteria there are. As the writer has said, in most instances there will be found Gram positive cocci and coli bacilli, the latter, of course, Gram negative. There is no necessity to make cultures on plates, and to isolate the bacteria, as this is a rather tedious process, and not easily applicable to clinical purposes. The easiest and simplest methods are the best. Then take an ordinary loopful of a platinum wire needle, the size of a small drop, that is, about a twenty-fifth of a c.c., either from the stab culture, if the growth is sufficient, or from the slant culture, or from both, and dissolve in 2 c.c. of sterile water, and inject the whole of it intraperitoneally into a mouse. If the animal happens to be small, half of it should be injected.

If the animal does not die, the bacteria are nonvirulent. If the cultures contain both virulent cocci and coli bacilli, the animal dies in about eight hours. Virulent coli bacilli alone will kill in from twelve to twenty-four hours, depending on the degree of virulence. If one wishes to go a little further, the mouse should be dissected and smear preparations from the blood of the heart and cultures therefrom should be made. The dissection should be made immediately after the death of the animal. If the smear preparations and the cultures contain only coli bacilli they are the only virulent microbes. If the injected cultures contain also virulent cocci, in addition to the coli bacilli, they can be recovered in the cultures from the blood of the dead mouse, but are hard to be detected in smear preparations, as the animal dies too quickly after the injection. If one suspects virulent cocci or anthrax bacilli, for instance, the injection is better made subcutaneously, not intraperitoneally, in which case death is not so sudden, and the bacteria develop better in the animal. Of course one can use two mice, one for intraperitoneal, and the other for subcutaneous injection. As was said before, the presence of cocci in the dead animal shows them to be virulent, as nonvirulent ones are destroyed in the body of the animal and cannot be recovered.

By remembering what was said before, we can conclude that the presence in the feces of virulent cocci, particularly diplo- and streptococci, as shown by the fact that they can be recovered from the dead animal, denotes a localized point of suppuration somewhere in connection with the intestinal canal, for in simple enteritis the cocci are, as a rule, nonvirulent, and the process is due to the colon bacillus, or some of its congeners.

This method is so easy and so simple of application that there is no reason why it should not be used very often, whenever there is reason for its use. In affections which are said to be due to autointoxication from the intestinal canal, such as giddiness, neuralgic pains, melancholia, etc., the toxicity of the intestinal bacteria should be tested. As has been said before, the ingestion of meat on the whole enhances the virulence of the coli bacilli, and they may be virulent in constipation as well as in diarrhea. In fact, in chronic catarrhal conditions of the intestines the two conditions are apt to alternate, and in constipation the danger of the toxins being absorbed into the system, as well as of localized affections, such as diseases of the biliary ducts and of the appendix, are greater and more frequent than in diarrhea.

The quantitative analysis of bacteria is a tedious and uncertain proceeding, and of little value. It is their virulence that is of importance. The writer has tried the injection of feces instead of cultures therefrom, but the results are apt to be misleading.

The same method should be applied to testing milk and other substances.

321 EAST THIRTEENTH STREET.

AN ORIGINAL INVESTIGATION OF AN EPIDEMIC OF GRIPPE, FOLLOWED BY A LARGE NUMBER OF CASES OF PNEUMONIA;*

WITH SPECIAL REFERENCE TO THE INFECTIOUS NATURE AND PERIOD OF INCUBATION OF THESE TWO DISEASES.

BY ALBERT WOLDERT, M.D.,
TYLER, TEXAS.

I DESIRE herewith to record eight cases of croupous pneumonia—pneumonia with consolidation (4 per cent. of the entire population), and upwards of 100 cases of grippe (or 50 per cent. of the entire population), and occurring during a period of six weeks, from February 14 to March 28, 1905, in a small rural district, Messer (Smith County), Texas.

As for the infectious nature and period of incubation of these two diseases, I believe that a report of these cases will be of special interest for the reason that the locality in which they occurred is one in which the inhabitants at this period of the year do not intimately come in contact with those living in cities, and who by such residence might have become exposed to more numerous sources of infection. Dwellers in the larger cities mingle with each other

*An address read before the Smith County Medical Society, held in Tyler, Tex., November 13, 1906.

to such an extent in public schools, parks, street cars, carriages, hotels, hospitals, and apartment houses, that the special focus, person, medium, or thing by which the infectious agent is spread renders the determination of the period of incubation of an infectious disease exceedingly difficult.

Of the 200 inhabitants of the above-named community the eight cases here reported were all those of croupous pneumonia occurring within the six weeks above noted. As far as can be learned there was only one case of pneumonia which was reported in this community during the corresponding period of the previous year. It might be of interest to say that during the corresponding period of the following year (1906), there were only a few cases of grippe (less than 10 per cent. of the population), which occurred in this same community, while not one case of pneumonia occurred. While about one-third of the population are colored, all of the eight cases occurred in the white race.

The community of Messer is situated in East Texas, and in a well timbered and well watered district. The country is quite rolling in character, the hills being upwards of 200 feet in height, with gradual slope in all directions. The soil for the most part is composed of very red and gray sandy loam, with clay subsoil lying as a rule within eighteen inches of the surface. The climate, according to Cline, is between "low damp warm and low damp cold." Extending from north to south lies a small valley, and traversing it in the same direction is the International and Great Northern Railway. The area of the Messer community is about two miles square, and within this area upwards of 200 people reside. The distance between the houses of the inhabitants ranges from 100 yards to half a mile. Agricultural and truck farming are the principal pursuits.

During the period from February 14 to March 28 the inhabitants had just begun to plow their lands, and were preparing the soil for planting corn, cotton, and vegetables. During this time the weather conditions had been unusually variable, marked by more or less sudden or sharp changes in the temperature, with an abundance of ice upon the ground and trees, and the soil was kept saturated with moisture.

The dwelling houses for the most part are constructed of pine lumber, one inch in thickness, while others are composed of logs, the interspaces being sealed with clay or pine boards. Many wide cracks exist in the floors and sides of the houses. Wood is the only fuel used; it is burned in large open fireplaces. These houses are ill suited to protect one against the icy touch of winter, and against sudden changes in the temperature.

One interesting fact should be recorded here, to wit, that during the previous fall, and throughout the winter, grippe had been more or less prevalent in this community. About March 7, 1905, grippe began to rage and within a month thereafter probably 50 per cent. of the population had suffered from this disease. By April 5, 1905, it had almost subsided, and by May 3, both grippe and pneumonia had totally disappeared. Therefore, in considering the infectious nature of croupous pneumonia as it seemed to have occurred in this community in the year 1905, it will be necessary to observe the relationship which seemed to exist between it and the grippe. The writer is aware that inflammation of the lungs may be induced by other pathogenic microorganisms than the diplococcus of pneumonia, such as the bacillus of bubonic plague and tubercle bacillus, and is also fully aware of the susceptibility to what is now called "croupous pneumonia" during an attack of grippe. The relationship which seemed to exist between these diseases will be considered subsequently in this article, first by the study of the individual cases of pneumonia, and later in the epidemic of grippe.

In presenting this report I desire to say that I hope that certain inferences, which now seem tenable, may be left open to me for proper revision and correction, should such prove to be erroneous by more complete researches on this subject. I believe, however, that a report of the cases will furnish additional evidence of the infectious nature of the two diseases—croupous pneumonia and grippe.

Cases numbered 1 to 8 under the head of "pneumonia" correspond to the same families numbered 1 to 8 under the head of "la grippe."

Case I.—The first case of croupous pneumonia which occurred in the Messer community developed on February 21, 1905, in the person of W. R., a boy nineteen years of age, who had during this season been exposed to grippe, but not to croupous pneumonia. On February 14 he had been out hunting when the ground was covered with snow and ice. On the following day he had a cold and two days later had a severe cough. On February 17 he had some fever, and two days later developed a pain in the chest. He was examined on February 21, and lobar pneumonia was found. He was ill of pneumonia for six weeks. The lower lobe of the right lung was consolidated. There had been no other cases of pneumonia in his family and no subsequent cases of pneumonia developed after his recovery. No other member of the family developed grippe after his recovery from pneumonia. This patient had grippe in February, 1904, and measles in April following. No member of his father's or mother's family had ever previously suffered from pneumonia.

Case II.—The patient, Mrs. T. B. S., was a woman, aged thirty-five years. She had not been in the same room with a pneumonia patient for eleven months. She was taken ill with grippe, February 27, but did not go to bed. Croupous pneumonia developed March 6, the onset being ushered in with a severe chill and high fever. When first seen by the physician attending her on March 7 she was expectorating large quantities of blood. The temperature ranged about 104° F. She was in the sixth month of gestation, miscarried on March 9, and died March 11. The entire left lung and lower lobe of the right lung were consolidated.

The patient had never previously had pneumonia. Her brother, many years before, had suffered from pneumonia, but had recovered. Her father had at one time had pneumonia.

On the evening of March 7 or morning of 8 her sister and her sister's child (aged eight years), then seemingly in perfect health, moved over to the patient's home to nurse her. On the third day after going to the patient's house this sister and child, together with the patient's husband and daughter (the latter, Case III.), fell ill of the grippe almost on the same day. The symptoms in these cases were cough, pains, through the chest, fever, laryngitis, and otitis media. The husband was sick one week, and the others remained ill for two or three weeks.

Case III.—This patient, M. A. S., aged nine years, was a daughter of the patient just mentioned (Case II.). She had been in the room with her mother, who developed pneumonia on March 6. About March 9 she developed grippe, and on March 11 or 12 croupous pneumonia came on, the upper lobe of each lung being consolidated. The patient

had fully recovered on April 11. Her grandfather on the mother's side had years before suffered with pneumonia, but had recovered. Her grandfather on the father's side died with pneumonia in 1883.

Case IV.—The patient, Mrs. J. B., was a woman aged 25 years. She had not been exposed to any case of pneumonia. About March 5 she developed grippe, but did not go to bed. Pneumonia developed with a chill at 1 A. M., on the night of March 12. When first seen she was expectorating large quantities of blood (temperature 104°), and the upper lobe of each lung was consolidated. She had a miscarriage (sixth month of gestation), on March 15, and died March 20. This patient resided about 200 yards distant from the home of her father's family in which grippe was prevailing, nearly every member of the family suffering with it. She had made many visits to this house during the time the inmates suffered with the grippe. She had never before suffered with pneumonia, and no member of the family had ever had the disease.

Case V.—The patient, R. B., was a boy, aged two years and two months, living with his mother (Case IV.), and had been exposed to both pneumonia and grippe. About March 1 he became ill with grippe (cold and cough), and on March 24, though he had not entirely recovered from the grippe, was removed out of the neighborhood a distance of some ten miles. Pneumonia developed March 28 and the child was seen by a physician only once, that being April 4; he found the lower lobes of each lung consolidated. Patient was complaining of pain in the chest, was breathing fifty or sixty times per minute, and had a temperature of 103° or 104°. Death occurred April 5. The child's mother died of pneumonia on March 20. One aunt, one uncle, and one cousin had suffered with pneumonia during this epidemic of grippe (see Cases VI. and VII., and also the case appended). The child had never previously had pneumonia.

Case VI.—Patient, C. B., was a woman, aged twenty-four who had nursed her sister (Case IV.) suffering with pneumonia. About March 8 the patient developed grippe (cough, cold, body pains, and perhaps fever), but did not go to bed. On March 18 she had a chill about 2 A. M., followed by croupous pneumonia, which ran a typical course. The upper lobe of the left lung was consolidated. Recovery occurred at the end of two or three weeks. The patient's father and mother had never had pneumonia. One sister, one brother, and two nephews had pneumonia during this epidemic of grippe. The patient had not previously suffered with pneumonia.

Case VII.—The patient, B. F., was a girl, eight years of age. About March 12 she began to have pains in the back and chest, cough, and fever. The tongue was dry, and parched. The bowels were constipated and the abdomen slightly tympanitic. A physician was called, and on March 18 examined lungs, but found nothing abnormal. On March 19 the lungs were again examined, and it was found that the left lung and lower lobe of the right lung were consolidated. The patient died on March 22. One of the patient's uncles on the father's side, and one of her uncles on the mother's side had suffered with pneumonia. The patient had never previously had this disease.

Case VIII.—The patient, E. B., was a man, aged about thirty years, who lived some twelve miles from the home of his sisters (Cases IV. and VI.). On March 22, while he was helping nurse his sister who had pneumonia, he developed grippe, but he did not go to bed. After the burial of his sister (March 20), he returned home, some twelve miles away. On March 28 he became wet by rain and during the night following he had a chill, followed by all the typical symptoms of pneumonia. The lower lobe of the left lung was consolidated. The patient fully recovered at the end of two or three weeks. This patient's two sisters (Cases IV. and VI.), and his nephew (Case V.), all had pneumonia during this epidemic of grippe. The patient had never previously suffered with pneumonia.

Case IX.—While the following appended case of pneumonia did not occur in the neighborhood of Messer, it may have some bearing upon the question of susceptibility of certain families in their relation to pneumonia. The patient was the son of the patient in Case VIII., the nephew of Cases No. IV. and VI., and a cousin of Case V. Or in other words, of this series of nine cases of pneumonia, four occurred in one family. This patient's aunt and cousin had died of pneumonia during this epidemic of grippe. The patient was a boy, aged three years, who lived with his father, twelve miles distant from Messer. The child had not been away from home, and had not been exposed to any case of croupous pneumonia. For a few days previous to March 29 he had suffered from a cough and cold. The patient lived in the same room with his father, who developed pneumonia on March 28. The patient developed croupous pneumonia on the following day, or one day later than the father. The lower lobe of the right lung was consolidated, and recovery occurred at the end of two or three weeks.

Did any of these cases of croupous pneumonia contract the disease from any of those afflicted; and if so, what was the period of incubation?

In considering these eight cases of croupous pneumonia above presented, it is found that out of this number there were four who had been exposed to other cases of croupous pneumonia, namely: Cases III., V., VI., and VIII. and in whom there was some possibility of infection from forms of pneumococci of sufficient virulence to bring on an attack of croupous pneumonia.

A summary of these four cases so exposed may be made as follows: Case III., M. A. S., was in a child nine years of age. Her mother had developed pneumonia March 5, and six days later pneumonia developed in the case of the child. Case V., R. B., was in a child two years of age. The mother had developed pneumonia on March 12, and sixteen days later pneumonia developed in this case. Case VI., C. B., was a young lady, twenty-four years of age, who had nursed her sister, who developed pneumonia March 12, and six days later she fell ill of this disease. Case VIII., E. B., occurred in a man, thirty years of age, and apparently in perfect health. On March 17 he went a distance of some twelve miles to nurse his sister, suffering with pneumonia, and himself developed pneumonia eleven days after his arrival.

In this series of four cases in persons who had been exposed to other cases of croupous pneumonia, the shortest possible period of incubation could have ben six days, and the longest possible sixteen days, or a general average of ten days.

In this connection it might be interesting to reiterate that in the following year (1905), though 10 per cent. of the population in this locality had grippe, not one case of pneumonia occurred.

The question of heredity, or those cases in which the parents or grandparents had previously suffered with pneumonia:

Case II.—Father several years previously had suffered with pneumonia.

Case III.—Grandfather on mother's side years before had suffered with pneumonia.

Case VII.—One uncle on father's side had pneumonia ten or fifteen years previously; and one uncle on mother's side had pneumonia six years previously.

Therefore, of this series of eight cases of pneumonia, heredity might have exerted some influence in 37 per cent. of the cases. No one in this series of eight cases ever previously had pneumonia.

The question of susceptibility of certain families towards this disease has already been noted, but it may be well to reiterate that of these eight cases (and one appended case), there were four which occurred in one family, though the patients lived in different houses.

The Part of Lung Involved.—Case I.—Lower lobe of right lung (recovered). Case II.—Entire left and lower lobe of right lung (died). Case III.—Upper lobe of each lung (recovered). Case IV.—Upper lobe of each lung (died). Case V.—Lower lobe of each lung (died). Case VI.—Upper lobe of left lung (recovered). Case VII.—Left and lower lobe of right lung (died). Case VIII—Lower lobe of left lung (recovered).

Age of Patients.—Case I., aged nineteen years; Case II., aged thirty-five years; Case III, aged nine years; Case IV., aged twenty-five years; Case V., aged two years; Case VI., aged twenty-four years; Case VII., aged eight years; Case VIII., aged about thirty years.

The fatal cases occurred in patients aged respectively thirty-five years, twenty-five years, two years, and eight years.

Mortality.—Of the eight cases here reported there were four deaths or a mortality of 50 per cent. This high mortality was doubtless due to the fact that those physicians who had charge of the fatal cases did not have the opportunity of seeing the patients as a rule in the early stages and could pay only infrequent visits to them, sometimes not oftener than once in every two days, and in one instance only one visit was made. In two of the fatal cases miscarriage occurred about the sixth month of gestation. In this series the writer of this paper treated only three cases (Cases VI., and VIII, and the appended case), and all the patients recovered.

After studying this series of cases of pneumonia it was found impossible to determine the possible source of infection in the first patient, since she had not been exposed to any other case of pneumonia. The disease evidently came on as a complication or sequela of grippe. Whether she harbored in the sputum the virulent diplococcus of pneumonia before the attack came on was not determined.

Pneumonia and Grippe.—From an investigation of the histories afforded by these eight patients, who suffered with pneumonia, it is believed to be probable that every one of them suffered from grippe for a few days previous to the onset of pneumonia. This assumption is based purely on the symptoms and clinical signs presented, since the microscope and cultural methods were not resorted to in any instance. In the absence of complete bacteriological examinations the writer is fully conscious of the errors which might occur from making such an assumption as this. He is also fully conscious of the errors which might occur in differentiating correctly between a "severe cold," and grippe, and also the prodromal symptoms of pneumonia by the clinical signs and symptoms presented in any given case.

The symptoms and clinical signs exhibited by the cases of grippe in this epidemic were as follows: Cough, pains through the chest, fever, laryngitis, otitis, bronchitis, constipation, and a considerable degree of prostration, lasting in some instances two or three weeks. In all the cases of pneumonia the grippe was the first to appear. In some instances the grippe persisted in the family while the pneumonia was in progress, and in certain families the grippe continued after the pneumonia had disappeared. In one family (Case VII.), there was only one case of grippe, and this was later followed by pneumonia, though there were several other members of the family, aged respectively, five, eleven, thirty-one and thirty-seven years.

The climatic conditions (snow and ice, with rain and changeable weather), was perhaps the principal cause in rendering the soil of man more fertile for the cultivation of the bacillus of grippe, followed in certain instances by the possible development of the virulent pneumococcus and consequent production of croupous pneumonia.

Grippe in the Douglas Community in Previous Years.—At different periods during the past few years, grippe has prevailed to a certain extent in this community. Quite a number of cases existed here during the month of February, 1904, while, as has been previously stated, a few cases persisted throughout the following winter and were prolonged into February, 1905.

Grippe in the Family of Case I. (see Pneumonia, Case I.), W. R.—About January 1, 1905, the youngest child in the family, aged eleven years, had grippe which lasted one week; the second case in this family was the next older, aged fourteen years, who developed grippe about January 15; the third case was in the mother, aged forty-two years, who developed grippe about February 1; and the fourth case was the patient, aged nineteen years (see Case I., Pneumonia), who developed grippe February 15 (after having been out hunting in the snow), and who developed pneumonia on February 21.

Possible Source of Infection.—In this family patients I. and II. slept together in the same bed and one developed grippe fifteen days after the first one became affected. Patient III. was the mother who slept in a different room. Patient IV. (who had both grippe and pneumonia), until the pneumonia developed, slept in an adjoining room with his brother, aged twenty-one years, but this brother never had the grippe.

The only members of the family who did not have grippe were the father, aged sixty years, and the son, aged twenty-one years. There were three cases of grippe in the family during February, 1904. They all occurred at the same time and the patients were aged respectively eleven, seventeen, and nineteen years. Two of these cases slept in the same bed. The possible source of infection in the first case perhaps could not be traced.

Grippe in the Family of Case II. (see Pneumonia Case II)., Mrs. T. B. S.—The first case to develop grippe in this family was the mother (see Pneumonia Case II.), aged thirty-five years. She developed grippe February 27, but did not go to bed. Croupous pneumonia developed March 6. On March 9 her husband and her son (the latter fifteen years of age) and daughter (aged nine years—see Pneumonia Case III.), and another daughter, aged four years, all fell ill of grippe about the same day.

Possible Source of Infection.—The husband and three children developed grippe ten days after it occurred in the case of the mother. In this family there was only one member who escaped the grippe. After this patient with pneumonia recovered no other cases of grippe developed. The source of origin of grippe in the case of mother is unknown.

Grippe in the Family of Case III. (see Pneumonia Case III.), M. A. S.—Was a daughter of Case II. (see Pneumonia) aged nine years. She and her father, and two sisters and a brother all developed grippe about nine or ten days after the mother first became ill of grippe. This patient had been in the same room with her mother (see Pneumonia Case II.) and on March 11 or 12 this patient developed croupous pneumonia. Her mother developed pneumonia five or six days previously.

Possible Source of Infection.—This patient became ill of grippe ten days after it had developed in the person of the mother. The possible source of origin of the disease in the case of the mother was not investigated. In this connection it might be well to state that the sister of Case II. and aunt of Case III. (see Pneumonia) about ten days after Case II. developed grippe, went over to nurse Cases II. and III. This sister who went to nurse the sick ones (the mother ill of pneumonia and child with grippe) took with her a little daughter, aged eight years, both of whom were in perfect health. Within three days after the two latter persons entered the house occupied by the sick, both of them developed grippe, March 9.

Grippe in the Family of Case IV. (see Pneumonia Case IV.), Mrs. J. B.—In this family there were five members, namely: the father, about thirty years of age, the mother, twenty-five years of age (see Pneumonia Case IV.), one girl aged six years, another girl aged four years, and a little boy, aged two years and two months (see Pneumonia Case V.). They resided about 200 yards distant from the home of Case VI. (see Pneumonia). The youngest child, aged two years and two months, developed grippe March 1 and was at the time sleeping with its mother. The mother, although in good health, continued to sleep with the sick child until March 12. Six days after grippe developed in the child the mother became affected with grippe (March 5) but did not go to bed, and on March 12 the mother developed croupous pneumonia. When the mother developed pneumonia (March 12) the child was taken out of its mother's bed and afterwards slept by itself in a cradle adjoining the bed. The mother died of pneumonia March 20. On March 24 this child was taken through the country a distance of some ten miles. It developed pneumonia March 28 and died April 5. The father during February and March was sleeping with the two children, aged four and six years respectively, and continued to sleep with them until the mother developed pneumonia on March 12. About March 1 the little girl, aged four years (and who was sleeping with its father) developed grippe and had a mild attack. This sick child for a few days continued to sleep with its father, and the other sister, aged six years, but it was later taken over to the home of its grandparents, some 300 yards distant. The other sister, six years of age, was then allowed to sleep by herself, but on March 10 developed grippe. The father, though at the time sleeping with the sick child suffering with grippe, and waiting upon both his wife and children, never developed grippe.

Possible Source of Infection.—Careful inquiry fails to reveal the possible source of infection in the first case, since no one suffering with grippe (or convalescent) had visited this family, and these patients had not gone to any place where grippe was prevailing. In the other cases occurring in this family the possible source of infection might more easily be traced.

Grippe in the Family of Case V. (see Pneumonia Case V.), J. B.—A boy, two years and two months of age. This case is the youngest one in the family referred to under the head of Case IV. (see Grippe) who developed grippe March 1, and has been duly considered above.

Grippe in the Family of Case VI. (see Pneumonia Case VI.), Miss C. B.—Of this family there were seven members living at home, namely: the mother and father and children, whose ages were as follows: the father, aged sixty years; the mother, aged forty-seven years; a daughter, aged twenty-four years, a son, aged twenty-one years; a daughter, aged seventeen years; another daughter, aged twelve years, and a son, aged eight years. They resided about 300 yards distant from the home of Case IV. (see Pneumonia and Grippe). The youngest boy, eight years of age, slept with his mother and father during February and March. The daughter, aged twelve years, slept alone, while the other two daughters, aged seventeen and twenty-four years, slept together until March 12. The first person to develop grippe in this family was the boy, aged twenty-one years, who became ill on February 28; the second person who became ill of grippe was the father, which occurred on March 3; the third patient was the mother, who became ill on March 6; the fourth case was the girl, aged twenty-four years, who became ill March 8, and who at the time was sleeping with her sister, aged seventeen years. While having the grippe she continued to sleep with her sister, but the latter person never developed grippe. The fifth patient was the boy, eight years of age, and who became ill March 15. This boy had been sleeping with his father and mother, both of whom had suffered with grippe a few days before he became affected. The only members of this family who never developed grippe were the daughters, aged twelve and seventeen years. The only member of the family who had grippe last year was Case VI. (see Pneumonia). After the pneumonia had subsided, March 27, no other member of the family developed grippe.

Possible Source of Infection.—In the first patient the possible source of infection cannot be traced, while in the other instances such sources of infection might perhaps be more easily done.

Grippe in the Family of Case VII. (see Pneumonia Case VII.), B. F.—The only case of grippe which occurred in the family during this epidemic was the patient, a girl, aged eight years, who developed grippe March 12 and pneumonia March 19. There were four other members of the family, aged, respectively, thirty-seven, thirty-one, eleven, and five years. No member of the family had suffered from grippe or pneumonia during the previous year. Five years previously three members of the family had grippe lasting two weeks. No case of pneumonia had occurred in the house for eight years.

Possible Source of Infection.—There had been no illness of any kind in this household since the previous June. Three weeks before the patient became ill she had spent the night at the house of a relative in which grippe was prevailing. For many months no one had visited her home who had previously been ill. The patient had been attending a school in the neighborhood in which the pupils were suffering from cough, and some perhaps were convalescing from grippe.

Grippe in the Family of Case VIII. (see Pneumonia Case VIII.).—E. B., was a man, thirty years of age. He was a brother of Cases IV. and VI. (see Pneumonia) and lived about twelve miles distant from them. On being apprised of the illness of his two sisters, he, on March 17, went to aid in nursing them. He stated that when he left home he was feel-

ing perfectly well, and there had been no illness in his family. He helped to nurse his sisters and on March 22, or five days from the time he began nursing them (one of whom had developed pneumonia on March 12, and the other one of whom developed pneumonia the day after his arrival), he fell ill of grippe. On March 23 he returned to his home and lay in bed two days, during which time he complained of having had fever, pains, and cough. He afterwards got up and went to work. On March 28 he became wet by rain, and during the night developed croupous pneumonia. His son, aged three years (see appended case of Pneumonia) sleeping in the same room with him, began to have a cough a few days previous to March 29, and on that day developed croupous pneumonia.

Possible Source of Infection.—Infection might have occurred while patient was nursing his sisters, five days before he fell ill of grippe. Whether his child (appended case) had grippe previous to the development of pneumonia is not known, but the circumstance at least looks suspicious.

The Possible Period of Incubation in These Cases of Grippe.—Of this series of cases of grippe the shortest possible period of incubation could have been three days; and the longest fifteen days or a general average of seven days.

In this epidemic of grippe age did not seem to exert any influence in regard to the susceptibility of the patient. In some instances the first one affected was very young, in another the first affected was middle-aged, and in still another instance the first one affected was quite old. Sex exerted no influence.

In reviewing this series of cases of grippe it might be impossible to determine the source of infection in the first case of grippe occurring in the Messer community, since the disease had been more or less prevalent throughout the winter. The prodromal symptoms of croupous pneumonia must of course be considered in analyzing these cases of pneumonia and grippe.

Conclusions from the Study of this Series of Cases of Croupous Pneumonia.—While it is granted that croupous pneumonia may arise or develop in persons who have not been recently exposed to any other case of pneumonia (such as in those who may carry in their sputum the virulent diplococcus of pneumonia), which event might perhaps occur after getting wet by rain, and while it is granted that the evidence furnished in this investigation is based purely upon clinical grounds not supported either by microscopic findings or cultural methods, and while the writer is fully conscious that the absence of such data renders these observations less conclusive than they otherwise would be, it is believed that from a careful study of this series of cases of pneumonia the following conclusions seem tenable:

1.—Infection of the human system by the bacillus of grippe so lessens the natural immunity, or prepares the soil of man, that subsequent infection by the virulent diplococcus of pneumonia and consequent production of croupous pneumonia may more readily occur.

2.—The possible average period of incubation of croupous pneumonia by air transmission is about ten days.

3.—The influence of heredity renders certain families more susceptible to croupous pneumonia.

4.—The rise and fall of a large series of cases of croupous pneumonia occurring within a limited time and locality, may be dependent to a large degree upon the coexistence of grippe.

5.—Pregnancy occurring during an attack of croupous pneumonia renders the prognosis more grave.

Conclusions from the Study of this Series of Cases of Grippe.

1.—While grippe appears to be an infectious disease, not all of those who come in direct contact (such as sleeping in the same bed) contract the disease.

2.—The possible average period of incubation of grippe by air transmission is about seven days.

3.—One suffering with grippe should be warned against the tendency to develop pneumonia.

4.—An infant suffering with grippe should not be permitted to sleep with a healthy mother, and when the mother is affected she should not be permitted to sleep with a healthy infant.

5.—The weather conditions, such as excessive rains with snow and marked variations in the temperature exert the greatest influence in the spread of grippe and consequent production of pneumonia.

6.—Age and sex exert no protective influence against grippe.

7.—Proper care should be exercised to destroy all sputa and fomites which may aid in the spread of grippe.

My sincere thanks are herewith tendered to Drs. B. T. Bryant and C. H. Willingham, of Whitehouse; Mrs. Sam Messer, of Messer, and Dr. J. Z. Ferrell, of Tyler, all of whom so kindly assisted me in compiling the data regarding these cases.

THROAT DISEASES CAUSED BY THE MISUSE OF THE VOICE.

By N. J. POOCK VAN BAGGEN,

THE HAGUE, HOLLAND.

EVERY specialist for throat diseases knows that very many of the sufferers from those affections are to be found among those whose profession demands constant use of the voice, as orators, clergymen, professional speakers, and singers. The clergymen's sore throat disease is known to every throat specialist. It is obvious that the misuse of the voice is in most of those cases the cause of the affliction.

The patient, after speaking or singing, will complain of a dry and hot feeling in the pharynx and the larynx, of irritation, and a frequent cough. It is only with the utmost exertion that the patient delivers his speech or song, and when the work is done he is hoarse or his voice gives out entirely. Gradually the evil increases, and finally the patient, singer, or orator consults his doctor in the hope of finding relief for his sufferings.

Examining those patients, we shall find the following characteristic symptoms: Catarrh of the pharynx and of the larynx, with congested and swollen mucosa. The pillars of the fauces are swollen and often highly developed. There is always paresis of the vocal cords which are red or yellow in color and which do not close well. The paresis of the vocal cords is mostly united with paresis of the m. cricothyroid anterior, the m. thyroid aryt. int., and the m. crico. aryt. laterales. In some serious cases a swelling of the arvepiglottic ligament is observed. Organic defects are not the cause in this case. They may be. It is known well enough that enlarged tonsils, adenoids, nasal polypus, or malformations of the tongue may be the cause of exertion in speaking, hoarseness, and loss of the voice. This is not the case here; the fault is purely functional. This is clearly proved by the

fact that as soon as the patient gives entire rest to his organ the affliction decreases and sometimes even disappears altogether, to reappear, however, as soon as the voice is used again in the wrong way.

Observing those patients while speaking or singing, we shall see that they do not use their breathing, articulation, and vocal muscles normally. There is no harmonious cooperation between those three groups of muscles; the faulty breathing and articulation fail to support the vocal muscles sufficiently, and are therefore an obstacle to the undisturbed vibration of the vocal cords.

As the breath is the chief element in the production of voice and speech, the patient has to learn in the first place the right way of breathing and how he may make the best use of the breath in phonation. Usually the breathing is clavicular in those cases, but even when the breathing is diaphragmatic the patient does not know how to control his breath and how to direct it. He lets it go as it will. Instead of striking the hard palate, the sound or vibrating air strikes the soft palate, whereby the tone is smothered as in a room hung with heavy curtains, and in order to make himself understood the orator or singer has to exert his voice to the utmost, while, if the breath is directed against the hard palate the voice is clear and carries to a long distance without any particular effort. The combined diaphragmatic and costal breathing is recognized as the best way of breathing. We get not only the largest amount of air and the best control of it in this way, but this is also the only way of breathing by which we are able to direct the breath consciously.

In regard to the articulation, we shall see the back of the tongue rising as a thick and heavy wall between the opening of the mouth and the pharynx. The consonants are not formed in the anterior part of the mouth with the tip or the middle of the tongue leaning against the hard palate, as is the right way, but the articulation is done way back in the mouth. K, g, and r are formed between the back of the tongue and the soft palate, or the pharynx.

The thickness of the voice tells us also that the action of the soft palate is insufficient; while the dullness of the voice betrays to us a lack of resonance caused by the swelling of the mucous membrane which lines the resonance cavities. However, those two defects just mentioned have to be considered as a result, but not as a cause of the disease.

As to the use of the vocal cords, we observe mostly an unnatural contraction of the muscles of the larynx. When pronouncing the vowel we hear constantly the shock or spasm of the glottis which means that the vocal cords are pressed tightly together by the pronunciation of each vowel. It is clear that this unnecessary effort is fatal to the already overstrained cords, and is not one of the least causes of the congestion of the larynx.

All speakers who misuse their organ must be specially warned not to take singing lessons to improve their speaking. The speaking has to be faultless before any good results in singing can be obtained.

It is superfluous to say that no exercises are to be undertaken before the patient has gone through a judicious medical treatment united with rest to the organ.

108 PLAATS.

Pregnancy and Abortions in Women Employed in Tobacco Manufactories.—J. Livon has investigated this subject. He refers to the opinions of various authorities who have been interested in the effect of tobacco on the pregnant woman. The opinions of these men vary. Among others, Brochard and Decaisne are convinced that women who work in tobacco manufactories are more subject to abortion than other women. Other observers, for example Ribemont and Lepage, do not believe in the harmful influence of tobacco on the progress of pregnancy or on the newborn. All observers are in accord concerning the considerable mortality of the newborn whose mothers work with tobacco. The larger number of deaths occur from the second to the fourth month. This is the period in which the mother resumes her work and gives the child, according to Vinay, nicotinized milk. A mother exposed in her work to the vapors of nicotine ought not to nurse her child. Her milk has a very pronounced odor of tobacco, although the presence of the poison has not yet been determined chemically.—*Revue Française de Médecine et de Chirurgie.*

Alteration of the Functions of Nutrition in the Nursing Infant.—G. Mya discusses the alterations in nutrition produced in the nursling by the use of cow's milk as a substitute for mother's milk. In some infants it agrees perfectly, especially when its use is not begun in the first months of life. In others, and when begun soon after birth, it produces affections of the digestive system, nervous system, skin, circulatory apparatus, and finally death from marasmus. The author believes that no single factor is the cause of these changes. The excess of casein, excess of fat, which being saponified uses up the alkalies of the body, the antagonism between the human and the cow's albuminoids, the changes due to sterilization of the milk, making it less digestible, may all contribute to the bad effects. Another factor is the rapidity with which the milk is taken, permitting the child to be easily overfed. Individual idiosyncrasy is an added factor in the causation of the evil effects of the milk. The liver has as one of its functions the reduction of alimentary and other substances, so as to render them innoxious in the circulation, and in the baby this power is slight. The weakness of the infant makes him succumb more easily than the adult to infections or general diseases. As to the treatment of such conditions, medicines should be little given. The indications are to change the diet so as to render it easily assimilable by the baby. Get him a wet nurse if possible. If not modify the milk, so as to render it easy of digestion.—*Rivista Critica di Clinica Pediatrica.*

Resistance of the Spores of Bacillus Anthracis.—Santi Sirena has shown that spores of anthrax, when dried in the hot sun in free air, live for nineteen days. In the thermostat in dry air they live 400 days. When dried by chemicals they live a longer time. Creolin up to 60 per cent. strength does not destroy them, but when used pure, they die in twenty-four hours. The bacilli are killed in fresh blood after ten minutes by 10 per cent. creolin, and after twenty minutes in the spleen of a diseased animal. In sterilized garden earth they lived fifteen years. In damp earth they lived four years. In earth saturated with moisture they lived thirteen years. In sea water they lived eight years. In sterilized water they lived more than eight years. In pregnant animals they passed from the mother to the fetus by way of the maternal and fetal placental vessels. They were found in the chorion, and in the placenta in great numbers. There were alterations of the muscular and epithelial layers of the uterus, consisting of hyperemia, dilatation of the vessels, and extravasation of blood. There were extravasations in the serotina also.—*Archivio per le Scienze Mediche.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 5, 1907.

MUNICIPAL CARE OF THE TUBERCULOUS.

THE active campaign which is being waged in this city against the spread of tuberculosis may be said to have had its actual beginning in 1894, when the reporting of cases of pulmonary tuberculosis in public institutions was made compulsory. This was supplemented in 1897 by an amendment to the Sanitary Code, in which the condition was included among infectious, communicable, and reportable diseases. The scope of this work has been gradually broadened, and it was early recognized that the establishment of a municipal clinic or dispensary would be of great assistance in the attainment of several most desirable objects. These were the early recognition and diagnosis of pulmonary tuberculosis, the intelligent supervision of patients under treatment, the continued observation of the indigent, the removal of suitable patients to a hospital, and the care of those suffering from laryngeal tuberculosis, which is among the most distressing and painful of complications. The first report of this clinic, which was opened in March, 1904, shows that the results attained have been most satisfactory, and one of the important features of the work is that almost fifty per cent. more patients were seen in the second than during the first year in which the clinic was open. This shows conclusively the value of the institution in bringing new cases to light, and many cases hitherto concealed were sent to hospitals, benefiting in this way both patient and family. Sanatorium treatment was also made available for a large number of incipient cases, and many other patients were assisted by the furnishing of an extra diet.

Although much has thus far been done with the means at hand in bringing tuberculosis under control, the authorities point out three essentials which must be carried out to complete this process. First and foremost comes the education of the people as to the nature of the disease and the procedures to be adopted to avoid its contraction; second, the early recognition of the disease and the removal to more favorable conditions of all sufferers, and third, the location and disinfection of all infected houses and premises occupied by the tuberculous subjects. It is only a public clinic, undertaken and supported by municipal agency, which can hope to enforce the suggestion of bringing patients suffering from tuberculosis under direct control, particularly those of the indigent class. It constitutes a form of paternalism in government which should be encouraged, however, rather than combated, as is unfortunately done in certain quarters. In addition to the help which it affords the needy, an institution of this kind should also serve as an object lesson to the profession in showing what can be done in the treatment of the disease with the means at hand. Too many practitioners still cling to medication as the essential in treatment, and neglect the many dietetic and physical measures which have been shown to effect the largest percentage of cures. The thoroughly scientific and ethical character of this public institution is well shown by the leaders in the movement, and the united and cordial support of the profession in this city should be extended to it in the effort to eradicate, if such a thing were possible, or at least to limit the spread of this destroyer of man."

THE EFFECT OF SALIVA ON BACTERIA.

IT is a well-known clinical fact that operative or traumatic wounds in the oral cavity have a tendency to heal kindly in all but exceptional cases. In explanation of this phenomenon it has been assumed that the saliva possesses bactericidal properties which serve to protect the individual against infection, although no one has come forward with any satisfactory experimental proof to sustain the claim. An attempt to solve the question has recently been made by Clairmont of v. Eiselberg's clinic in Vienna, who investigated the bactericidal properties of the saliva in animals and the human subject. His results, which are published in the *Wiener klinische Wochenschrift*, November 22, 1906, form an interesting contribution to the subject and show that the salivary secretions can be depended upon to furnish a certain degree of protection to the organism.

When wounds of the oral cavity heal by primary union, this fact, according to Clairmont, may be ascribed primarily to two conditions, viz., an unsuitable local environment and the mechanical cleansing action of the salivary flow. No specific bactericidal action of the saliva could be detected in tests made with the pathogenic germs of typhoid fever or tetanus, or with staphylococci, streptococci, or the colon bacillus, nevertheless a small number of organisms will find here such unsuitable conditions present for extended growth that they are soon destroyed. In this respect the saliva may perhaps be compared with physiological salt solution. Animals seem to have these properties much more markedly developed than human beings. Aside from individual variations, differences in the secretions of the submaxillary and of the parotid glands could be determined in the case of most of the species examined. The former produces saliva which seems to have but little or no effect at all on bacterial growth, while that from the parotid of both man and animals has a well-marked inhibitory action on the same, so that a considerable number of bacteria may be destroyed. It was found that the most intense effect was present in goats and other ruminants, and that the pyogenic organisms suffered to the greatest extent. In culture experiments, however, the addition of a favorable medium to the saliva seems to offset whatever inhibitory action may have been manifested by the salivary secretions. If the latter, in either man or animals, are artificially stimulated the resultant fluid will after a time be found to be perfectly sterile or to contain only a very small

number of organisms, which soon perish. Another curious fact which was noted in the course of these experiments was that the excised suppurating parotid gland showed a remarkable resistance to decomposition.

The observations made by Clairmont afford us some ground for believing that the conditions present in the oral cavity constitute an important element in the protection of the organism against infection from without. If this is so it is possible that the protective action may be increased by stimulating the salivary flow and washing away various culture media which would otherwise favor bacterial growth. This is probably of more importance than any bactericidal action which the saliva may exert.

UTERINE RELAXATION.

An atonic condition of the uterus has been observed under various circumstances, but most commonly perhaps during the puerperal state. Kossmann some years ago directed attention to the fact that it may also occur in nonpuerperal women during or after the operation of dilatation and curettage, and since then various explanations have been advanced to account for the phenomenon. The most probable of these is concerned with a local congestion of the uterus due to the operative invasion which also results in a relaxation of the uterine blood-vessels. The accompanying increase in the blood pressure is then believed to result in a straightening of the tortuous vessels which carry the relaxed muscle along in this process. The whole uterus swells and straightens out like an erectile organ while the cavity is distended. If the tone relaxation of the vessels and that of the muscle remain entirely coordinated the phenomenon will end as it began—simultaneously; the congestion disappears and the muscle contracts. Should there be, however, an incoordination, which is readily possible when the irritation is artificial instead of physiological, the congestion may disappear before the muscle regains its tone, the expansion remains and the condition becomes one of complete atony.

This condition of uterine atony in the nonpuerperal state as the result of dilatation and curettage probably occurs quite frequently, but is not recognized or the operator assumes that perforation has taken place. The subject is discussed in a recent paper by Maier in *Surgery, Gynecology, and Obstetrics* for December, 1906. In reporting several cases the writer draws attention to the practical interest and value of a definite knowledge of this fact. Dilatation and curettage are probably among the most frequently performed gynecological operations. For this reason it is well to bear in mind the acute changes which may take place in the uterus at this time and not to be too hasty in assuming that perforation of the organ has taken place when the condition is merely one of atony. Unless this fact is borne in mind, an abdominal operation may often be undertaken in cases in which, after dilatation, the curette suddenly slips into the uterus to an apparently abnormal degree.

Another possibility, to which the writer does not call attention, however, which may result from this atonic condition of the uterus, is the entrance of irrigating fluid through the Fallopian tubes into the abdominal cavity. The fact has occasionally been referred to, and in isolated instances in which a laparotomy has followed curettage, the fluid has actually been demonstrated free in the peritoneal cavity. This phenomenon may be explained in the same way, and a knowledge of the possibility of the accident should lead to the exercise of great care in douching the uterine cavity; and to the use of absolutely sterile and nonirritating solutions for the purpose, so that if they do gain entrance into the abdominal cavity a minimum of harm will result.

A New Suture Material.

The disadvantages inherent to most of the suture materials in common use are too well known to require rehearsal, but several new methods of preparing silk for this purpose, founded on what appear to be rather important considerations, described by Wederhake in the *Münchener medizinische Wochenschrift*, December 4 and 11, 1906, seem of more than usual interest. After a lengthy disquisition on the physical properties which render silk, catgut, and silver wire undesirable as routine materials for buried sutures, the author describes several new forms of suture material which he says possess decided theoretical and practical advantages. The first of these is the so-called silver silk, which is intended for use as a ligature material in small sizes only, and not for buried sutures. Its advantage is that it possesses powerful and lasting antiseptic properties. It is prepared by rendering the silk fat-free by extraction with ether and absolute alcohol, sterilizing by boiling in 1-1,000 aqueous solution of bichloride of mercury, immersion in a 10 per cent. peroxide of hydrogen solution, and treatment for several hours with an alkaline silver solution, by means of which it becomes impregnated through and through with metallic silver. This silver solution is made by adding potassium hydrate solution to a 1 per cent. solution of silver nitrate and dissolving the resulting precipitate in ammonia. As a last step the material is again sterilized by boiling in bichloride solution. The author is of the opinion that a material intended for use in buried sutures should not be permeable by fluids, and in order to effect this he impregnates silver silk prepared as above with caoutchouc. The silver silk is dried, is soaked in chloroform, and is then immersed for from two to twelve hours, according to its size, in a 16 per cent. solution containing 8 grams of caoutchouc in 50 c.c. of chloroform. This material also can be sterilized by boiling in bichloride solution. Silk prepared in this way is not only impermeable to fluids, and therefore not likely to become infected in the wound, but is stronger than the corresponding size of ordinary silk and than the silver wire ordinarily used for suturing. The third of the author's innovations is an absorbable silk. This is prepared in a manner similar to that used in making parchment paper. According to its size the thread is treated for from twenty seconds to four minutes with concentrated sulphuric acid, is washed with water, is dehydrated in alcohol, and is then subjected to a hardening process by means of tannin and absolute alcohol. This silk is said to be as strong as untreated silk and is rendered flexible by treatment with glycerin. It can be sterilized by boiling in bichloride solution, and when buried in the tissues it is completely absorbed at the expiration of from four to six weeks. It would require too much space to reproduce the author's theoretical discussions concerning these

suture materials, but while it may be that others will not be as successful in their practical applications as he has been, they at any rate represent a promising attempt to solve what has been one of the greatest difficulties in operative work.

Primary Carcinoma of the Appendix.

Although in this country the consensus of opinion among surgeons is in favor of inspecting the appendix in all laparotomies in which this is possible and of removing it when any abnormalities are present, this doctrine has not yet apparently gained acceptance in Germany. At least Landau makes a strong plea to this effect in a recent number of the *Berliner klinische Wochenschrift* (December 10, 1906), taking as his text the occurrence of primary carcinoma of the appendix. So far he says sixty-four cases of malignant disease of the appendix have been reported, and he considers that the lesion will be observed much more frequently in future now that more and more attention is being directed to it. In Landau's own case the laparotomy was made for the purpose of enucleating a uterine fibroid and of removing a tube and ovary. The appendix was found stiff and sharply bent on itself with a somewhat enlarged extremity, and was therefore removed. It was not until microscopical sections had been made that the condition was recognized as one of typical carcinoma simplex. Landau, therefore, urges upon his colleagues the rule to inspect the appendix whenever possible, and states that in order to do this he has come to resort more and more to laparotomy instead of vaginal operation. If the organ appears to be healthy both on inspection and on palpation he does not interfere with it; but if there are any evidences of disease, or if the history points even remotely toward appendicular involvement, it should be removed without hesitation.

Suboccipital Tuberculosis.

A surgical operation of unusual difficulty is described by Payr in the *Deutsche medizinische Wochenschrift*, December 13, 1906. It consisted in the removal of considerable portions of the atlas and adjoining structures owing to tuberculous disease. The patient was a woman of thirty-five years, who, eighteen months before the operation, manifested the first evidences of the lesion, consisting in enlargement of the cervical glands and pain behind the ears and in the nape of the neck. Later on, stiffness, dysphagia, and a retropharyngeal abscess developed, and at the time of operation, in addition to a profusely discharging cervical sinus, there was a communication of the abscess cavity with the pharynx. For the details of the operative procedure by means of which the diseased areas were extirpated, and which, of course, presented many technical difficulties, the original must be consulted. The postoperative course was uncomplicated, the extensive wound healed without sinus formation, and now, about a year later, the patient is still free from any evidence of impending relapse and is able to do all her own housework. While, as the author points out, the conditions under which an operation of this sort can be carried out with hope of a radical cure are no doubt but rarely encountered, the fact that even occasionally a patient can be freed from a lesion that must otherwise lead to a miserable death is a sufficient incentive to stimulate the daring of surgeons.

The Geographical Distribution of Gastric Ulcer.

It is a well-known and long recognized fact that certain diseases of the stomach are more prevalent in certain localities than in others, that their symptoms likewise assume varying degrees of importance, and that complications which are prevalent in one place are scarcely ever found in the other. In a recent book Rütimeyer has subjected these facts to a critical analysis, using for the purpose not only his own series of over two hundred cases, but also a large number of extracts from the literature on the subject. This investigation shows conclusively that the frequency of gastric ulcer varies within wide limits in different countries, and that even in a relatively restricted geographical section differences may exist in its constituent parts. The clinical symptoms also vary considerably in men and women, hyperacidity and hemorrhages being more common in the former than in the latter, in addition to a number of other distinctions. Hyperacidity also varies as it seems with the locality: in Zurich, for example, about 20 per cent. of the cases of gastric ulcer are attended by this symptom, whereas in Geneva, not so very far off, nearly 100 per cent. of the cases are thus characterized. These facts are of general interest, and if they can be further developed can perhaps also be made of practical interest in the treatment of this condition, for if climatic influences exert themselves on the progress of the lesion in the manner indicated a knowledge of this favorable effect is of considerable value.

News of the Week.

Memorial to Dr. Christian Fenger.—Original research work in all branches of medicine is to be fostered by an organization in memory of Dr. Christian Fenger. The Fenger Memorial Association for Medical Research was incorporated at Springfield, Ill., recently, the incorporators being Drs. Frank Billings, Ludwig Hektoen, and Karl Doepfner. The plan is to raise a fund of from $5,000 to $10,000 to be used in encouraging medical students to take up original research work in bacteriology, surgery, and other branches of medicine.

Dr. Charles S. Benedict, upon his retirement, on December 31, from the Health Department after twenty years' service in the division of contagious diseases was presented with a silver service by thirty of the men in this department who have served a good part of the time with him. Dr. Darlington presented the gift.

The Weber-Parkes Prize and Medals.—Mr. Edward Liveing, the Registrar of the Royal College of Physicians, London, announces that the next award of these prizes will be made in 1909, and that the adjudicators have selected as the subject of the essay for that occasion: "The value of bacterial products in protecting against or in curing tuberculous diseases, with special reference to pulmonary tuberculosis in man." All essays, together with any preparations made in illustration of them, must be transmitted to the Registrar of the College during the last week of May, 1909, in accordance with the regulations relating thereto, copies of which will be forwarded from the college on application. The award will be made at some time previous to October 18 in that year, on which day the prize and medals will be presented to the winners.

Death Rate at Panama.—The report for November of Colonel Gorgas to the Isthmian Canal

Commission shows that during this month there were sixty-six deaths among the employees of the commission in Panama. This is as against 113 deaths in July, the decrease being largely due to the lessened mortality from pneumonia. Among the 5,000 American employees there were only three deaths. Among the whole population in Panama, employees and others, there were 241 deaths, as against 422 in July.

Brain Surgery and Moral Qualities.—According to the newspapers a fifteen-year-old Cleveland boy who was operated on some time ago by trephining in order to correct moral deficiencies supposed to be the consequences of a depression of the skull due to an accident received in early childhood, has lapsed into his former evil ways. For a time the operation appeared to have been successful in restoring his moral control, but then as the result of the fall of a hammer from a height his head was again injured, and now he is a bad boy again.

To Control Immigration.—A commission to investigate the existing legislation relative to immigration has been appointed by Secretary of Commerce and Labor Straus. The law which regulates steerage accommodations on steamships coming to this country was passed in 1882, and since that time the changed conditions of ship building, etc., have made many alterations desirable in order to conform to the requirements of the times.

A Remedy for Mountain Sickness.—In a recent communication to the *Revue Scientifique*, Professor Agazzotti announces that he has been able to prove that the sole cause of mountain sickness is the rarefaction of the air, and that by administering a mixture of oxygen, carbon dioxide, and nitrogen the symptoms can be entirely prevented.

Bubonic Plague.—Owing to the presence on board of a Lascar seaman suffering from what he officials suspect may be bubonic plague the steamer *Kybfels*, which arrived last week in Philadelphia from Calcutta, is being detained at quarantine. In the week ending November 3, the day the *Kybfels* cleared, there were seven deaths from the plague in Calcutta and eighty-three cases and fifty-six deaths in Bengal. The *Kybfels* got a clean bill of health at Calcutta, but a suspicious death occurred on the voyage.

"Brooklyn Medical Journal"—In its December issue this journal contains the announcement that with the close of the year 1906 its publication will cease. During the twenty years of its existence the journal has been prominent in reflecting the medical activity of the Borough of Brooklyn, and has been the official organ of the Medical Society of the County of Kings. Its editors have been Drs. William C. Braislin, James P. Warbasse, John A. Lee, and Clarence R. Hyde.

The Craig Colony.—Dr. Wm. T. Shanahan has been promoted to the position of First Assistant Physician and Dr. Kirby Collier has been promoted to the position of Second Assistant Physician in this institution, both promotions to date from January 1, 1907.

Death of an Oldest Inhabitant.—On December 28 patient No. 7 of the Middletown, N. Y., State Hospital died after having been an inmate of the institution for thirty-two years. He was the oldest patient of the hospital, having been the seventh to be admitted after the institution was opened.

The Chicago Home for the Friendless, by the will of Otto Young, will receive $20,000, and the Chicago Home for Incurables $400,000.

Donation to Cancer Fund.—On the occasion of their golden wedding Mr. and Mrs. Henry Louis Bischoffesheim of London distributed $500,000 to various charities, and of this sum the Imperial Cancer Research Fund received $200,000.

The Scranton Typhoid Epidemic.—From thirty to forty new cases of typhoid fever daily have been reported from Scranton, and on December 26 the total for the month was 751 cases, and for the epidemic 791. The hospitals are all overcrowded, and even their emergency accommodations are taxed to the utmost. The epidemic is believed to have originated from water from the Elmhurst dam.

Tuberculosis Exhibition.—The Committee on the Prevention of Tuberculosis of the Charity Organization Society will hold a tuberculosis exhibition at the Twenty-third street branch of the Young Men's Christian Association, 215 West Twenty-third Street, beginning Wednesday, January 2, and lasting until January 10. Numerous public lectures, illustrated with stereopticon views, are to be given by various speakers. The exhibition will be open all day, and admission will be free.

Washington Heights Hospital.—The entire medical board of this institution has resigned, but four of its members have been reinstated by the Board of Directors. These are Drs. Nathan, Frisner, Sable, and Clarence E. Sichel. Early in January the hospital will be removed to 165th street, near Broadway.

Beth Israel Hospital.—At the seventeenth annual meeting of this organization it was announced that $76,500 had been contributed toward the erection of the new hospital building. According to the report there were during the year 1,353 free patients treated out of a total of 2,377. More than 1,000 applicants had to be refused because of lack of facilities. There were 72,712 consultations and 81,841 prescriptions given. The actual hospital expenses were $83,492 and the total expenses $114,000. This included $30,000 for improvements.

Western Reserve University of Cleveland.—President Charles F. Thwing, of this University, announces that a chair of experimental medicine has been established in the medical school, and that Professor George N. Stewart of the University of Chicago, has been appointed to the professorship. The funds for this purpose and for the endowment of a laboratory have been provided by two gifts of $100,000 each, made by Mr. H. M. Hanna and Col. Oliver H. Payne.

American Association for the Advancement of Science.—At the closing session of this association, held in New York, December 31, the following officers were elected for the coming year: *President*, E. L. Nichols, professor of physics at Cornell University; *General Secretary*, F. W. McNair, president of the Michigan School of Mines; *Secretary of the Council*, Prof. William Harper Davis, of Lehigh University. Besides these ten vice-presidents were elected. A banquet was given the retiring president, Prof. W. H. Welsh, at the University Club by the members of the executive council.

Comanche County (Okla.) Medical Society.—This society has elected the following officers for the ensuing year: *President*, Dr. A. N. Campbell; *Vice-President*, Dr. M. A. Jones; *Secretary and Treasurer*, Dr. J. L. Lewis.

Dickinson and Iron Counties (Mich.) Medical Society.—Officers for this society have been elected as follows: *President*, Dr. F. Larson, Crystal Falls; *Vice-President*, Dr. Libby, Iron River;

Secretary and Treasurer, Dr. H. Sethney, Crystal Falls.

Jefferson County (Tex.) Medical Society.—At the annual meeting of this society, held at Beaumont on December 18, the following officers were elected: *President*, Dr. H. A. Barr; *Vice-President*, Dr. A. A. Bailey; *Secretary and Treasurer*, Dr. R. R. Sullivan.

Farmington (N. H.) Medical Society.—The physicians of this town and vicinity have organized under the name of the Farmington Medical Society and have elected the following officers: *President*, Dr. G. W. Ellison; *Vice-President*, Dr. R. J. P. Goodwin; *Secretary*, Dr. P. H. Greeley; *Treasurer*, Dr. H. P. Wheatley.

Neosho (Kan.) County Medical Society.—Officers for this society for the following year have been elected as follows: *President*, Dr. J. C. Lardner; *Vice-President*, Dr. M. A. Duncan; *Secretary*, Dr. W. K. Mathis; *Treasurer*, Dr. A. M. Davis.

Kent County (Mich.) Medical Society.—At its recent annual meeting, held at Grand Rapids, the following officers were elected by this society: *President*, Dr. S. L. Rozema; *Vice-President*, Dr. William Fuller; *Secretary*, Dr. H. Alden Williams; *Treasurer*, Dr. F. C. Warnshuis.

Kankakee (Ill.) Physicians' Club.—At a regular meeting of this club the following officers were elected: *President*, Dr. G. H. Lee; *Vice-President*, Dr. T. E. Caron; *Secretary-Treasurer*, Dr. C. K. Smith.

Obituary Notes.—Dr. Walter Judson of New Haven died on December 25, at the age of eighty-seven years. He had been visiting a patient, but slipped on the pavement and fell, and shortly afterward died of cerebral hemorrhage. He was born in Bristol, Conn., and was graduated from Yale in the class of 1864. He received his medical degree from the College of Physicians and Surgeons in this city.

Dr. Timothy H. Bishop of New Haven, died of pneumonia on December 26, at the age of seventy years. He was graduated from Yale in 1860, and had practised in New Haven for many years. He was a member of numerous historical and geneological societies.

Dr. Frank E. Beckwith of New Haven died of apoplexy on December 27, at the age of fifty-nine years. Dr. Beckwith was born in Norwich, Conn., and was graduated from the College of Physicians and Surgeons in 1871. He practised in this city until 1880, and was then appointed to the chair of obstetrics at the Yale Medical School. In 1885 he relinquished this position and devoted himself exclusively to private practice.

Dr. Francis E. Doughty of this city died of pneumonia on December 28, at the age of fifty-nine years. He was born in Albany and was graduated from the College of Physicians and Surgeons in the class of 1869. He was consulting surgeon to the Hahnemann, Flower, and Laura Franklin Hospitals.

Dr. L. W. Babcock of Wadena, Minn., died on December 25, at the age of sixty-six years. He was Speaker of the Minnesota House in 1903.

Dr. William Steward of this city died on December 24 in the Brooklyn Hospital. He was born in England and received his medical education in the Bellevue Hospital Medical School. He was actively interested in medical missionary work.

Dr. John C. Sanders of Cleveland, O., died at the age of eighty-two years, on December 23, as the result of injuries due to a fall on an icy pavement. In 1882 and 1883 he served as president of the American Institute of Homeopathy and had practised for fifty years in Cleveland.

Dr. J. W. Mount of Kansas City died on December 18 at the age of sixty-eight years. He had practised in Kansas City during the past twenty years.

Dr. William H. Hipp of Chicago died on December 19 of pneumonia. He was born at Berrien Springs, Mich., in 1864, and was graduated from the Bennet Medical College in 1885. He had been surgeon at the Cook County and Chicago Hospitals, and was a member of the State Board of Health.

Dr. John MacDonald of Chatham, N. B., died on December 18 after a lingering illness. He was born at Mount Stewart, P. E. I., fifty-six years ago, and was a graduate of St. Dunstan's College, Charlottetown, and the Jefferson Medical College of Philadelphia. He had practised in Chatham for about twenty-five years.

Dr. A. J. Dooley of Marion, Ind., died on December 18, at the age of thirty-four years. He was a graduate of the Rush Medical College in the class of 1897, and had practised in Marion ever since.

Dr. William H. Huger of Charleston, S. C., died on December 17 at the age of eighty-one years. He was graduated from the South Carolina College in 1846 and a few years later from the Medical College of South Carolina. He completed his medical education in Paris and then returned to Charleston, where he had practised ever since. Two years ago he completed a half century of service to the Charleston Orphan House and was presented with a silver bowl in commemoration of this event.

Dr. Clark Leavitt of Danville, Ill., died on December 19 after a long illness. Dr. Leavitt was born in 1833 and received his medical education at the University of Ann Arbor, from which he was graduated in 1861. After practising in Newport, Ind., for sixteen years, he removed to Danville, where he had practised ever since.

THE FIFTH HARVEY SOCIETY LECTURE.

The fifth lecture in the present series given by the Harvey Society was delivered at the Academy of Medicine on Saturday evening, December 15. The speaker, Dr. S. J. Meltzer of this city, chose for his topic "The Factors of Safety in Animal Structure and Animal Economy." He began by defining what was meant by factor of safety, and illustrated the use of the term in the construction of buildings, bridges, and machinery. All of these, as was well known, were constructed of more than sufficient strength to bear even the extraordinary strains to which they might be subjected. Such construction, however, was not economical.

To what extent was the animal body provided with factors of safety? The speaker said that although there were quite a number of facts bearing on this point, no one, so far as he was aware, had ever approached the subject from just that point of view. Just this, however, was really an advantage, for then one might feel sure that the facts were without prejudice. We all knew that nature, above all, was economical; factors of safety, as already pointed out, were not economical. Was the animal body constructed to work with the greatest economy, or were factors of safety provided?

Safety provided for by excess of structure was well exemplified in the bilateral organs. If one of the kidneys were excluded the loss was compensated by the other. The increased work was taken up immediately without any noticeable impairment. It was possible to remove as much as two-thirds of

each kidney without ill effect. The normal secretion of the kidney, it was pointed out, was not nearly the maximal capacity; the margin was at least twofold. The lungs were organs of supply and elimination. In spite of their important work, life was possible with the major portion of the lung tissue consolidated or destroyed. In pneumonia and empyema death was due not so much to mechanical interference with respiration as to toxemia. Halle had completely removed the right lung of rabbits —more than half of the respiratory organs—without deleterious effects and without altering the respiratory quotient. In the lungs, then, there was a large factor of safety in the amount of lung tissue provided. This was not really excessive when we considered the importance of this function. The speaker next cited the tissues of the generative organs as another example of quantity in excess of that apparently required. Small pieces of the organs left after surgical removal were capable of functionating normally. It had even been recorded that pregnancy had occurred after supposed double ovariectomy. These cases had been explained by assuming that a tiny piece of ovarian tissue had been left behind. In operations on the young, if fragments of the organs were left behind after removal, the sexual character was normally developed. This had been well shown by experimental work on cocks.

In the thyroid gland the removal of four-fifths or five-sixths was not followed by the symptoms produced by complete removal of the organ, symptoms of cretinism, etc. In other words, one-fifth or one-sixth of this gland, or a single small accessory thyroid, sufficed to carry on the functions of the larger structure. Complete removal of the adrenal glands was followed by death in from thirty-six to forty-eight hours. If, however, only a tenth of a large gland or a small accessory one were left the functions were normally maintained. Here the margin of excess capacity was at least ten times the normal requirement.

Going on next to the nervous system the lecturer pointed out that the brain did not follow the rules just indicated. This structure should be regarded rather as a number of isolated functionating organs than as a single bilateral organ. It was not really bilateral; the right motor area, for example, controlled the muscles of the left side. However, this division did not hold for the centers of muscles of respiration, of deglutition, etc. Thus if only one of the vagi were cut the normal respiratory rhythm was maintained. If both were severed the inhibition of the rate of the heart beat was abolished, while the respiratory muscles were paralyzed. One vagus, therefore, was sufficient so far as functional capacity was concerned, yet two vagi were provided.

The same provision for safety was found in the unsymmetrical organs. Complete removal of the pancreas resulted in glykemia and glycosuria. If but a tenth of the organ were left behind, however, the animal would be completely protected. Removal of half of the liver did not interfere with its many important functions; in fact, as much as three-fourths could be removed without special ill effects. The stomach could be completely excised, or as much as 70 to 80 per cent. of the small intestine removed without necessarily interfering with normal health. It had recently been suggested that functionally the colon was almost useless to man.

A similar abundant provision was found in the products of tissue activity. Thus in the digestive enzymes we had pepsin, trypsin, and Cohnheim's erepsin for the digestion of proteids, ptyalin and amylopsin for carbohydrates, steapsin and gastric lipase for fats. The last mentioned enzymes were also present in the liver and bile. The amount of the enzymes secreted was also far above that really required, and it was known that most of them could be excluded, individually, from the digestive tract without noticeable effect on nutrition.

It was interesting, the speaker said, to see how well nature safeguarded the reproductive functions. For the sexual functions of a woman about 500 ova were all that could possibly be used. At birth the ovary of a female child contained perhaps a hundred thousand ova, and even at the time of puberty there were still some thirty to forty thousand. Similarly, in the male, there is an enormous production of spermatozoa. It had been calculated that an average ejaculation contained several million spermatozoa. Only by providing this enormous excess was nature certain to overcome the many obstacles in the passage of the spermatozoon to the ovum, and so provide for a continuation of the species.

It was strange, at first sight, to see how scantily in this respect certain vital functions were provided for. This was particularly exemplified in the medulla, where slight mechanical injury caused serious damage. On the other hand few of the organs were so well protected mechanically from external violence, and few possessed such an abundant vascular supply.

Factors of safety were also provided in the circulation. There was, for example, more blood in the body than was actually required. One-half of it could be withdrawn without serious consequences, and the loss was rapidly and easily replaced. The relation of the volume of the blood to that of the vessels, and the fact that the blood can easily be thrown into the splanchnic areas, the skin, or the working muscles, were also factors of safety. So also was the existence of collateral vessels which might be called upon in an emergency. The heart possessed a superabundance of force and volume.

The speaker then called attention to another method of furnishing a margin of safety, namely, by providing multiple and parallel mechanisms. The principle was well exemplified in the several vasomotor centers, *e.g.* the main one in the well-guarded medulla, and subordinate and compensating centers in the dorsal cord, in the sympathetic ganglia, and even in the vascular wall itself. Central as well as local mechanisms were also provided for the heart, the intestines, and the uterus. In the pancreatic secretion and in the formation of milk we had examples of chemical-stimulating mechanisms supplemented by nerve control. Pancreatic and gastric proteolysis, and water elimination by the sweat glands, kidneys, and mucosa were examples of coexisting mechanisms. The distribution of work among several groups of tissues so that some act as reserve forces was also a factor of safety. Self-repair, regeneration, hypertrophy were factors of safety peculiar to living forms, and these processes tended not only to replace or compensate injured and used tissue material, but to maintain and restore margins for safety beyond present or normal requirements.

Did principles of economy or those of superabundance prevail in nutrition? There was a reserve of oxygen, and glycogen and fat were saved for unforeseen emergencies. A storing up of proteid food did not occur except in convalescence, in the spawning of fish, etc. Dr. Meltzer believed that a diet containing more available proteid than that advocated by Chittenden was desirable, for this would be in accord with the existing principles of

maintaining a large margin of safety in the animal body. Chittenden's *a priori* assumption that the smallest amount of proteid on which the animal body could regularly maintain itself would be the most desirable, was, Dr. Meltzer said, quite unwarranted and seemingly opposed to the principles above enunciated.

Correspondence.

THE SCIENTIFIC CRITERION OF A MALIGNANT TUMOR.

To the Editor of the Medical Record:

Sir:—In view of the publication by Dr. Clarence C. Rice (Medical Record, November 24, 1906) of a case of laryngeal cancer, treated by injections of pancreatic ferments, the time seems opportune for a few words upon the matter looked at from the standpoint of the scientific investigator. Dr. Rice in his paper only states that it was "supposed to be carcinomatous," and I am given to understand that this point and the fact that no pathological examination was ever made before treatment (rightly in my scientific opinion) have been seized upon by the critics. What do they suppose it might have been? No number of injections of pancreatic ferments would ever have the slightest effects in diminishing the size of a benign neoplasm, for such a thing is composed of normal or somatic tissues, not of "imitation tissues," like a malignant tumor. The true nature of a malignant tumor is a question to be determined by scientific methods, and at this juncture it is fitting that the scientific investigator should place himself in front of the physician, announcing his determination to defend the latter against all attacks. Well, the scientific investigator steps confidently into the arena, the sword of science is now held ready to strike; it has no scabbard to throw away, its point is sharp, its edge keen. The hand grasping it and holding it aloft knows how to use it!

During the past few weeks (November, 1906) the pages of a medical journal in Great Britain contained several letters upon that neoplasm of the mouse, commonly known as "The Jensen Mouse-Tumor." The controversy, originally started by Mr. W. Roger Williams, F.R.C.S., raged at first around two points: (1) its nature and whether it was or was not a true cancer, and (2) the justification of applying to it the name of its finder, and thus of naming it "The Jensen Mouse-Tumor." In the sequel, apparently, the first point was lost sight of, and the original writer and Mr. Henry Morris, President of the Royal College of Surgeons, narrowed the discussion to the second and more trivial point as to whether Moran's or Jensen's name should be applied to it. Looked at from the strictly scientific point of view, it should not be called by either name. Like the chameleon, "the creature's neither th' one nor t'other!" In anatomy, at all events, that system of nomenclature has been abolished.

But the original question, raised by Mr. W. Roger Williams, touches much graver issues. He denies that this tumor is a cancer at all! If this conclusion be right, it is not very flattering to the scientific acumen of any one of all the investigators of cancer, who have used or still employ this neoplasm in their work. In the *Centralblatt für allgemeine Pathologie* (Vol. 17, p. 870) the pathologist, F. Henke, now of Konigsberg, states the results of his critical examinations of this and other now well-known mouse-tumors. The paper was read before the German Pathological Society at its meeting in Stuttgart on September 18, 1906. Obviously, Mr. W. R. Williams was not present, for Henke's verdict met with no contradiction! Briefly, his conclusion was that the Jensen mouse-tumor, like the others examined, was a true cancer, and analogous to a human carcinoma.

We have here the diametrically opposed views of two experienced pathologists. My concern is not with the conclusion arrived at by Henke, but with that advanced by Mr. W. Roger Williams. One might, indeed, surmise that there was no pathological criterion for a cancer. What is the criterion for the statement that this mouse-tumor is not a cancer? Scientific reasons are not contained in the original report of his lecture in London or in his letters to the medical papers. The criterion for his judgment is simply his authority. The Jensen mouse tumor is not a cancer, because—he says it is not! As he stated in *The Lancet* of 1904 (December 3, p. 1613) regarding other aspects of the problems of cancer, he is satisfied, he has convinced himself, he has stated his conviction, that the Jensen neoplasm is *not* a cancer. "Damit Punktum!" as the Germans say.

Is this or is it not a scientific question? Are or are not the pages of the chief medical newspapers in Great Britain open (unpaid) to the pens of all scientific men? I am well aware that they are not open freely to mine! Matters have reached a climax, when scientific questions are disposed of in this arbitrary fashion. It is the kind of "argument" which authority always employs. "I know far more about the thing than you do!" But—it is not "science." One is reminded of some of the things—wonderful things they were—contained in a leader in *The Lancet* of February 4, 1905, and written by one who did not understand the difference between a scientific fact and a conjecture. "In short, Dr. Beard passes from one conjecture to another. He begins by views on embryology, which on his own showing are not generally accepted by embryologists. He goes on to express opinions on the histology and the pathology of cancer which are not in accordance with known truths and launches into the realm of therapeutics with assertions about the action of ferments which would inevitably cause the rejection of a candidate in physiology." The lack of commas in these passages is quite characteristic of the writings, up to date, of him who wrote these highly complimentary things. Since that time he has himself adopted, *without acknowledgment*, two of the "opinions," *i.e.* conclusions, expressed by me, that of the "mimicry" of the tumors, and that of the identity of cancer and sarcoma. As to the rejection of a candidate in physiology, perhaps he is not aware that in the year of my birth, 1858, it was held by physicians and physiologists that the sweetbread, or pancreas gland, had no *digestive functions*, and both Corvisart and Kühne, who were the first to describe the functions we now assign to it, also ran this serious danger of rejection, but as they had no intentions of being examined in physiology, they did not mind running the risk. It is nothing less than a gross insult to the intelligence of a scientific man of nearly twenty-five years' standing to say such things regarding his work. He is not a paid official researcher. As if, too, the "generally accepted" in science were of necessity true! From 1870 to 1900 a somatic origin of germ-cells, based on the researches of Waldeyer, was "generally accepted," but in 1902 Waldeyer, like the great man of science that he is, withdrew his researches, and thus took away all the basis of this general acceptance. The view is now without any basis in observation, *but it is still "generally accepted"* because it fits in with other human superstitions.

The writer is not a pathologist, and probably he would never have felt deeply concerned about the sayings of pathologists had they not invaded the realm of biology and embryology. The proceedings of the Stuttgart meeting are full of both biology and embryology—of a sort—biology and embryology, which only exist in the human pathological imagination. However, this writing is not intended to be a treatise on either science, based in actual observation. To come to the point at issue. What is the pathological criterion of a cancer? Now, in asking this question I have no desire to raise a storm about anaplasy, metaplasy, and all the other words, not things, ending in "plasy." Therefore, the question may be put in another form: What is the *scientific* criterion of a cancer?

There is now a pretty general agreement that a growth made up of normal tissues and containing hair, skin, teeth, and bones is a more or less reduced individual, an embryoma, a twin identical with the individual harboring it. Can any similar conclusion be reached regarding a cancer? Is it germinal in nature, as some have insisted? Where is the criterion? If it be germinal in nature, it should form eggs or sperms, or both, but it never does so. Unless it be due to a parasitic organism, as it is neither somatic nor germinal, it can only be one other thing. For of the life-cycle there only remains trophoblast. *Cancer is an irresponsible trophoblast.* If this be true, where and what is the criterion? The criterion is, that if it be trophoblast it cannot live in the presence of the secretion of the pancreas gland, especially in that of the ferment or enzyme, trypsin. The chemical test (*exact science*) of cancer is its behavior, when living, toward injections of extracts of real, *not imaginary*, pancreatic ferments.

As these words are written one seems to hear certain surgeons and official researchers remark, "We have tried trypsin, and it has no action upon cancer. It is useless." Softly! Wait a little! As an Italian physician said: "I have given any number of injections of trypsin in a case of cancer of the tongue, and the thing calmly pursued its 'parabola,' its course." The reply made to this gentleman in choice (?) Italian was: "Yes, and nearly all the time you were acting in opposition to my scientific advice, while a similar cancer of the tongue further south in your own country was gradually healing." I will not invoke the microscopical evidences, but will instead refer to the numerous human patients, who have been, or are being, treated with hypodermal injections of pancreatic ferments, which are guaranteed to be what is printed of them on the labels of the boxes. From many of these cases I have

noted, and some physicians have agreed, that it is an easy thing to kill every cell of an ordinary unoperated cancer, even a matter of a few weeks, but not at all easy to remove the dead tumor. In the presence of sufficient trypsin, and this is not a large amount, no cell of an ordinary unoperated cancer can live. Where is the proof? Recently I was informed of two cures in New York, one a cancer of the larynx, the other a cancer of the tongue. The former has been reported, and possibly by this time the latter also. "None in Great Britain?" Not yet, for most of them are like the one which ran its parabola in Italy, and for the same reason, because the wrong stuff was employed. "Two only, then." *Two human lives saved!* Add to these some others who will be saved, as well as a certain lady in South Italy. She had suffered from the torments of "inoperable" cancer of the tongue since January, 1903. She is the mother of a large family of children, all living and healthy. Early in March, 1903, the lady was examined, cancer of the tongue diagnosed, operation at first advised, but afterwards declined, by Dr. Guiseppe Caccioppoli, Professor of Operative Medicine and of Clinical Surgery in the Regius University of Naples, Surgeon to the Hospitals for Incurables and Loreto, and she was also examined and the like diagnosis given by Dr. Cavaliere De Giacomo Annibale, Professor of Operative Surgery in the Regius University of Naples. The pancreatic treatment (injectio trypsini and injectio amylopsini, Fairchild) was undertaken under the scientific directions given by me from time to time, by Gennaro Cavaliere Guarracino, Physician and Surgeon to the Provincial Hospitals for the Insane of Naples, and to the Hospital of St. Eligio, and by Professor Michele Manzo, Surgeon to the Pilgrims' Hospital. In the opinion of these two latter the last of the cancer is gone, but she has lost most of her tongue, which the two eminent surgeons hesitated to try to remove. By the end of September the last remains of the cancer came away. The chief physician wrote confirming this, and added: "This is a wonderful result, and I declare that it seems to me the most considerable fact which our science has ever obtained." Long ago he promised me his full notes with a view to their publication in English. *That is the scientific criterion of a cancer—the chemical test!*

Certain British surgeons and others have obtained only negative results. Why have they not reported them? The reasons for their failures would then have been apparent. Some of them tell patients that they have tried trypsin and found it "useless in cases of cancer." How do they know that they were using trypsin? Have they ever tested, as a chemist must do his reagents, the injection as to its ferment powers? Are they sure they were not using something little, if any, better than glycerin and water? As well might a brewer assert, "I have tried yeast, and it won't act upon the wort of my intended brew of ale. It is quite useless for brewing beer." I and others have tested all the injections advertised, and I have seen the results of assays. The finds are astounding. My published scientific work lays down that the injection should be "the secretion of that important digestive gland, the pancreas," that is to say, be prepared from the fresh gland direct, that this injection should contain all the ferments, that, generally speaking, it should be given for not a very great number of weeks, and be followed by injections of amylopsin, the diastatic ferment of pancreas gland, to remove all the bad symptoms of "eclampsia"—a thing it has done again and again, and never failed.

Two persons claimed to have discovered that "the proteolytic ferment of the pancreas, and not the diastatic" converted glycogen or animal starch, and acting logically on this "discovery," they put out, the one selling and the other using, an injection of trypsin so pure that it had no action upon glycogen or animal starch! When in 1905 I wrote of the secretion of the pancreas gland, do those who have failed imagine that I really meant the dispensing in a chemist's back shop of somebody's trypsin in powder, just as though it were so much blue pill? There is only one set of preparations now on the market which satisfies the above requirements. Before they put out their injections the makers of this preparation, and they alone of all the makers, asked my opinion of their procedure. All their products are stable and aseptic. There are in my house, as I write, ampoules of injection, which, if taken out of the thrice-sealed box, would be found to be—so much glycerin and water!

Those surgeons who have described the treatment as "useless" have actually never employed it. They are really in the same logical "scientific" position as one of their colleagues in Chicago, Dr. Nicholas Senn, who frankly condemns it as "a failure," while admitting that he has never tried it! (*Chicago Tribune*, August 5, 1906.) He might just as well declare that yeast will not ferment the wort of beer, and state at the same time that he has never made an experiment with yeast to test its supposed powers in this direction! Surely this is *not* a sample of science, "made in Chicago!"

The criterion of a cancer, the exact chemical test, is not, let me insist, its behavior toward a glycerin and water solution of ferments in powder, but toward an extract of fresh pancreas gland, scientifically prepared. Unless "boiled" or otherwise spoiled, such an injection can never be described as "useless."

All this is not merely a criterion, but it is *the criterion*, and no other is possible. Therefore, one does not need to ask the surgeon named in the opening passages of this writing to produce a criterion, for he has none, any more than Dr. Nicholas Senn has, except in each case his "authority." Science, sad to say, does not recognize this as valid. By the chemical test the mouse-tumor, known as Jensen's, is a malignant neoplasm, a cancer, for it is killed and its albumin pulled down by the ferment, trypsin. That is *a fact* of comparative physiological chemistry, *an exact science!* It is not open to the contradictions of any surgeons living, least of all to those of Mr. W. Roger Williams and Dr. Nicholas Senn.

In the same way the "supposed cancer" treated by Dr. Rice according to the scientific method of treatment revealed by my work, is now proved to have been a true malignant neoplasm, for the chemical test has demonstrated its nature. It is no argument to the contrary to assert that other cases failed to yield. Chemical experiments do not always succeed at the first attempt. I have known the two great men of science, who taught me chemistry, Sir Henry Roscoe and the late Professor C. F. W. Krukenberg, to fail often, but in the end they *always* succeeded. In cases of failure, some of the conditions needed for the success of the experiment may be absent.

EDINBURGH. JOHN BEARD, D.Sc.

OUR LONDON LETTER.

From Our Special Correspondent.

BRADSHAW LECTURE — EOSINOPHILE PLEURITIS — INFECTIVE TUMORS OF DOGS—CHOREA—NOMENCLATURE OF DISEASES—ELECTION TO GENERAL MEDICAL COUNCIL—LEAGUE OF MERCY—ACTION AGAINST SURGEONS—OBITUARY.

LONDON, December 14, 1906.

THE "Bradshaw Lecture" was delivered on Wednesday at the Royal College of Surgeons by Mr. Edmund Owen, V.P., who took for his subject "Cancer: Its Treatment by Modern Methods." He laid down emphatically that in the present state of our knowledge the only way of dealing with it is by prompt and thorough removal. As soon as a surgeon has made up his mind that a growth is malignant and could be removed, no time should be lost. No surgeon, from a desire to lessen mental distress or allay the dread of his patient, should be led to consent to any dallying with any problematical treatment. Surgery could not go in advance of facts, and at present she could not promise cure, whether by cutting operation, by *x*-ray, by Finsen's light, or by any drug. Treatment was not the same thing as cure. The most effectual treatment of cancer, however small, was the knife. It was owing to the freedom and thoroughness of operations that great advances had recently been made. Our forefathers would have been astonished at the thoroughness of modern methods of operating. To them the presence of enlarged glands was almost a bar to interference. But men and women have now no greater powers of resistance than fifty or a hundred years ago. The triumphs of modern surgery, to put it figuratively, might be ascribed to Lister having shown the virtue that lay in soap and water and the nailbrush. In the world of therapeutics there were dark tracts and continents which could only be discovered by men of imagination and energy. When the happy discovery should be made it would not be by columns of figures and percentage calculations, which like pancakes must be served quickly or be spoiled. Percentages might be of value worked out by an actuary in a life office, but were hardly the same when compiled by a surgeon to set forth the result of his treatment, for two patients with a disease called by the same name were not of the same clinical value, nor were twenty nor two hundred. The sooner surgeons discarded the activarial method of setting forth progress in connection with cancer, the better. Speaking of the excellent work of the Imperial Cancer Fund, the lecturer referred to the patient, hopeful work of the Director, Dr. Bashford, and his staff. He regretted that their researches were running the risk of being hampered by the limited space in which they worked and the inadequate skilled assistance the fund could afford. It was likely that experimentation on mice would be mentioned at a meeting of the Vivisection Commission, and some misinformed and therefore apprehensive witness, or some little Englander of the scientific world might be asking himself what profit can come from such

experimentation, claiming that mice are of more value than many human beings who are or may be the subjects of cancer, and demanding that further experimentation—the only means by which a cure is likely to be discovered—shall forthwith cease. As to the precise value of the work it was too early to speak; but seeing into whose care the direction of the laboratories had been placed the result might be awaited in full assurance that no cruelty would be allowed to dishonor the research.

Regretting that it was not possible to call attention to any method of treatment which could honestly and confidently promise a cure, as surgery at present knew of none, Mr. Owen added that nevertheless the surgeon would do a great deal for his patient; might be able even to set him free from his disease. But the word "cure," if ever used, should at present be uttered only in a whisper as it were; though perhaps later it might be proclaimed from the housetops. Disheartening as it was to be obliged to confess that at present no certain cure had been discovered, and that, so far as known, the searchers were not obviously on the track of one, yet the public might be assured that if ever a cure should be found those who are strenuously working at the subject would be in immediate possession of it. If the exact position of affairs could be placed before the public it might induce more people to give financial support to the National Fund for the promotion of cancer research and might also prevent some who fear they are attacked from falling into the hands of so-called "cancer-curers."

At the Pathological Society, on the 4th inst., Drs. Perkins and Dudgeon contributed an account of a case of eosinophile pleurisy. A girl of twenty-two attacked with bronchitis and acute pleurisy in a few days developed acute pericarditis, and, twenty-two days after admission to hospital, endocarditis. By aspiration nine ounces of yellow fluid were removed from the pleural sac. Cytological examination showed 34.6 per cent. of coarsely granular polymorphonuclear eosinophiles in a count of 500 cells, 10 per cent. polyneutrophiles, 23 per cent. small lymphocytes, 32.4 per cent. epithelial cells. Examination of the blood at the same time gave leucopenia, slight anemia, eosinophilia, and increase of mononuclear cells. Staphylococcus aureus, and albus were cultivated from the sputum. A blood examination six weeks later showed absence of eosinophiles, a normal number of leucocytes, and a normal differential count. Autopsy showed pleural adhesions on both sides, adhesions, pericarditis, and vegetations on the mitral and aortic valves. No sign of tuberculosis in any part of the body. No positive information was obtained as to the source of infection, and the authors suggested it might possibly have been influenzal.

Dr. Seligmann exhibited a number of infective venereal tumors of dogs from British New Guinea. It could not be said the dogs were of pure native breed, as there had been too much crossing with those introduced, but the natives said the disease was known before white men came there. The tumors were considered as most probably identical with those described by Bellingham Smith and Washbourne. The position, microscopic appearances, and transmission were the same. An important point was that in one instance metastasis had occurred to the testicles, both of which were completely replaced by new growth which, however, had not penetrated the tunica albuginea. Mr. Shattock considered this last point particularly interesting, the testicles showing real metastasis and not extension by continuity with the prepuce. The tumors presented perfect histological pictures of large, round-celled sarcoma with no signs of inflammation. That they were contagious did not prove them not malignant. Contagiousness and infectivity were only relative terms. The tumors should be classed with sarcomata, and it might be that the investigation of such ambiguous forms or connecting links would eventually lead to a knowledge of the pathogenesis of cancer.

At the Therapeutical Society Dr. Cecil Wall read a paper on the value of certain drugs in chorea. The effects of different methods of treatment were compared, the criterion adopted being the number of weeks before the choreic movements ceased. Under arsenic it appeared that the duration was the same as under no treatment. Under sodium salicylate the result was very little better. Under acetosalicylic acid the duration was much less. In half the cures the movements ceased in less than a month; in 92 per cent. in less than two months. Under arsenic the movements continued for over two months in 62 per cent. of the cases. Dr. Duncan said that in the North of England they obtained excellent results with arsenic, and he suggested that probably in the south there was some difference in the disease or else in the temperament of the children.

Dr. A. F. Hertz then read an elaborate paper on the importance of a salt-free diet in the treatment of edema and serous effusions.

The third revision of the fourth edition of "The Nomenclature of Diseases" is being issued this week. The work may be considered official, as its primary use is for the purposes of the registration of diseases, and to this end the elaborate index is of the greatest value. It is to be feared indeed that many practitioners confine their attention to this, consulting the work only as the necessity of certifying a death may recur. But the book is full of information in a condensed form and represents no small amount of the most recent advances in our views. The preparation of the first edition dates back to 1859, the second to 1880, the third to 1892. This fourth was begun in 1902. At the meeting of the Royal College of Physicians, Sir William Church presiding, in July of that year, it was determined to begin the decennial revision, to be issued in 1906, and here it is before the year has expired. All along it has been the production of a committee appointed by the college, representing not only its own fellows but the public services, the universities, and most medical authorities. There is also a very strong "subcommittee on classification" and twenty-three other subcommittees (worthy of two persons) for the revision of the classification of local diseases. The Latin, French, and German translations have engaged three separate scholars. Mr. Shattock, the Latin reviser, has adopted a plan deserving of the highest commendation, selecting as far as possible Latin equivalents which would be readily understood should the language again become an international medium of communication. Moreover, he has not followed the absurd plan of Latinizing proper names, but treats them as indeclinable—though when a Latinized name has been established he sometimes admits it as a synonym. A memorandum by the classification committee reminds us that the large, heterogeneous section, headed "General Diseases" in the third edition, has been broken up into the following groups: (1) Infective diseases, (2) intoxications, (3) general diseases not included in the two preceding groups, and (4) certain morbid conditions incident to various parts. These embrace conditions which do not necessarily affect the whole organism, but which it is desirable for registration purposes to return under a general rather than a local heading. They are Malformations, New Growths, Cysts, Effects of Injuries, of Parasites, of Poisons, and of Foreign Bodies.

An action against two surgeons at Cardiff for negligence was tried last year at the local assizes, and the jury could not agree. A second trial was wanted and held last week in the high court, and the jury, after three or four times reporting that they could not agree, at last gave a verdict to the plaintiff with £100 damages instead of £2,000 asked for. The case was one of a bicycle accident causing a dislocation of the humerus, complicated with extensive bruising and swelling, concealing at first a fracture of the surgical neck of the humerus. This was found with Roentgen rays, but the danger of gangrene prevented active manipulation, and a pad in the axilla, and bandaging the arm to the side, was considered at the consultation the best course. The patient recovered with some stiffness of the shoulder, for which with a patient's gratitude he sought a solatium of £2,000, and Messrs. Rose, Pepper, and Balke gave evidence for him, though they were opposed by Sir F. Treves, Sir W. Bennett, and Messrs. Bowlby, Moullin, Lane, Page, Owen, and Waterhouse. An appeal is expected, so not much may be said. I hear that the costs of this trial are expected to be £6,000 or £8,000—a scandal to the law which permits it, and lawyers who profit by it. If doctors are to be subjected to these dangers in obscure cases they will have to demand an indemnity before proceeding to treat the sufferer.

As I anticipated, the British Medical Association has carried its three nominees at the election of representatives to the General Medical Council. I have nothing to say against the three gentlemen chosen except that they represent—instead of the electorate—the British Medical Association, which is always striving to get everything under its control. But the profession is to blame, for, like the grumbling ratepayer, it is too apathetic to vote. The elections have regularly declined in interest so far as votes show. The highest number polled this year is below that of unsuccessful candidates ten years ago. Another rather discreditable circumstance is the inability of so many electors to fill up the voting paper, notwithstanding most explicit directions which accompanied it. Out of the 12,828 voting papers sent in, 911 were returned through the dead-letter office, 615 voters had not signed the identification envelope, and 467 had not fastened it, 193 had not put the voting paper in the envelope, 105 sent in too late, and 35 had not properly marked their paper with the cross only.

The League of Mercy is making great progress. The annual meeting of the presidents of districts was held on Wednesday, when it was stated that probably a sum of £17,000 would this year be handed to the King's Hospital

Fund. This will bring up the total obtained by the league in its eight years of existence to £80,000.

Dr. W. T. Greene died on Monday. A highly-cultured man with a fine literary taste, he was also a naturalist of wide attainments and a special bent toward ornithology. His great work on the "Gray Parrot" is probably known to you. Smaller books on birds of various kinds fell from his ready pen, and he also wrote some stories and verses for magazines which displayed delicate and refined taste. He practised for many years in a southern suburb and later in a western quarter of London. Possessed of an attractive personality and courteous manner, his patients had the greatest confidence in his skill, and well they might, for in some branches he was more than up to date and had forestalled certain advances. He was partly educated in France, where he took the degree of Bachelor in Letters. Afterward he entered Trinity College, Dublin, and took the A.M. and M.D.

Mr. R. S. Fowler, F.R.C.S., of Bath, where for many years he had enjoyed the confidence of a wide clientele resorting to that famous spa, died on the 9th inst., aged seventy-six.

Lieut.-Col. C. R. Bartlett, R.A.M.C., died on the 5th inst., aged forty-seven, at Sierra Leone, where he was senior medical officer. He saw service in the Ashanti Expedition of 1895-6, and two years later on the North-western Frontier, India.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE CHOLERA EPIDEMIC OF 1905, ITS ORIGIN, AND THE MEANS TAKEN TO SUPPRESS IT—LEPERS IN PANAY—PERSONAL.

MANILA, November 10, 1906.

THE regular monthly meeting of the Manila Medical Society was held November 5, 1906, at 8.30 P. M. at the St. Paul's Hospital. Dr. McDill demonstrated a number of cases, among others a case of carcinoma of the uterus, and stated that his experience of the past year confirmed the earlier reports that carcinoma was not very prevalent in the Philippines. This experience is in conformity with the generally-accepted statement that carcinoma does not occur with the same frequency in tropical climates as it does in temperate ones.

The first paper of the evening was read by Dr. Victor G. Heiser, Director of Health for the Philippine Islands, entitled "The Outbreak of Cholera in the Philippines of 1905, and the Methods Used in Combating It, with Statistics to January 1, 1906." He stated that in the pandemic which ended March 8, 1904, there were 166,252 cases, with 109,461 deaths reported, but that reliable observers were of the opinion that at least one additional case occurred for each one that found its way into official records. From March, 1904, until August, 1905, there were no cases known to have occurred, but suspicious cases, which clinically resembled Asiatic cholera, were encountered from time to time. All those that came under notice were carefully autopsied and bacteriologically examined by such competent observers as Dr. Richard P. Strong, of the Bureau of Science (Bureau of Government Laboratories), with negative results. The first recognized case of the present outbreak occurred in the person of a prisoner in Bilibid Prison. The next case occurred outside the prison in the person of an American woman residing in the Walled City; the next case was that of an American residing in the Santa Cruz district, a distance of over a mile from the first case, the two persons having nothing particularly in common. At the same time suspicious cases were occurring at Fort William McKinley, which is located about seven miles up the Pasig River from Manila, with symptoms which were attributed to vino poisoning, but later definitely diagnosed as cholera.

Cases then occurred in Manila as follows: August 23, 2; August 24, 1; August 25, 3; August 26, 8; August 27, 10, and thereafter an average of about ten cases per day until about the middle of September.

The characteristic tendency of the outbreak continued during the early weeks of the scourge, *i.e.* no connection could be traced between cases; no two cases occurred in any one house, nor did any two cases occur in any one group of houses, neither did more than one case occur at a time in any one section of the city. It was pointed out that during the first two weeks of this outbreak there had actually been more cases than during the same period of the outbreak of 1902, which went to show that the disease was virulent in character, and that perhaps the principal reason that it did not reach the proportions of the epidemic of 1902 was probably due to the measures employed in suppressing it. After the presence of the disease in Manila was recognized it was learned that it had made its appearance about a week earlier in a small town called Jalajala, in Laguna Province. A review was then given of the foreign ports which had direct steamship communication with Manila. From the evidence it appeared that the disease was probably not introduced from without, but was rather a recrudescence.

Numerous tables were exhibited, showing the number of cases by age, race, nationality, occupation, etc. The table by race was the most interesting, and is given in full:

Race.	No. of cases.	No. of deaths.	Mortality.	Ratio of 1 case to.	Date of last case. 1905
Americans	11	6	54.0	399.	Oct. 10
Filipinos	220	200	90.9	802.6	Dec. 31
Chinese	4	4	100.0	5,307.5	Oct. 8
Foreigners	20	16	80.0	227.	Nov. 8

From the above table it will be seen that in proportion to their number more foreigners contracted cholera than any other group; that the Americans ranked next, but had the lowest death rate, and that the smallest number occurred among the Chinese. The mortality of 100 per cent. among the Chinese may be attributed to the very few cases that occurred among them, and that those who recovered probably escaped detection by the health authorities. This immunity among the Chinese is particularly noteworthy, because it is, in all probability, due to their firmly-established habit of drinking tea instead of water, and not eating raw vegetables.

That no further cases occurred among Americans after October 10 was probably due to the fact that as soon as they believed the disease to be actually present they observed the prophylactic measures against cholera more strictly.

In mapping out the campaign for combating the disease the work was divided into four parts: (1) The isolation of the sick in the cholera hospital, and rigid disinfection of their houses and effects; (2) protection of the city water supply, including the closing of wells located in the City of Manila; (3) the prohibition of the sale of foodstuffs likely to become contaminated, and the proper protection, by fly-screens, of the remainder; (4) the education of the public in the precautions to be observed in order to avoid the disease.

Particular stress was laid upon the fourth part of the work: the education of the public, and the success in controlling the outbreak was no doubt due to the cooperation which was given. In order to place something practical before the public sixteen simple rules for combating cholera were printed in the newspapers, and then issued in the form of a handbill in English, Spanish, Tagalog, Ilocano, Visayan, and other native dialects. The Bureau of Education sent these circulars to every teacher in the Islands, with instructions that the rules should be taught to the pupils until they could recite them, and then the pupils were requested to repeat them to their parents. The Archbishop of Manila sent the circulars to all priests, with instructions that they explain their contents to their parishioners, and the churches of other denominations did likewise. In addition, large, flaring posters with the rules printed in the different languages were displayed in the postoffices, municipal buildings, and other places throughout the Islands. Later a more advanced cholera circular was prepared for the use of teachers, and the information contained in them enabled many of the American teachers to cope successfully with cholera when it made its appearance in the towns in which they were working.

By the above means many thousands of Filipinos soon learned that they could easily avoid contracting the disease, which was an entirely different attitude from that displayed in the epidemic of 1902, when only fatalistic indifference was shown, and the only measures taken by the natives themselves consisted in nightly religious processions. This time, with the exception of a few instances, in the districts in which dense ignorance prevails, the religious processions were scarcely ever encountered.

The following conclusions were given: (1) From the evidence obtainable at this time it is impossible to state whether the cholera was reintroduced into the Philippines or whether it remained here in some latent form during the year and a half in which no cases were detected; (2) while there is no evidence to show that the disease spreads by other means than that of enteric fever, yet the rapidity with which it makes its appearance in many widely separated places puts it in an entirely different class so far as combating it successfully is concerned; (3) that maritime quarantine can practically insure the prevention of its spread by sea; (4) that it is practically impossible to make land quarantine effective, hence it is useless to engender the opposition with which it is usually met, and the time and money required by quarantine will yield much better results by the education of the public in the manner in which the disease spreads; (5) that education of the public is a much more effective measure in the suppression of

cholera than methods that depend upon force for their application. (6) In order to make a serious outbreak of cholera in the Philippines impossible it will be necessary to replace the present insanitary water supplies with artesian wells, or other sources by which infection from surface drainage cannot be effected, or to correct it by filters or other means where it occurs.

The collection of the lepers from the Island of Panay was successfully accomplished, and over three hundred were landed at the Leper Colony at Culion November 1. The officials in charge of collecting the lepers report that many persons who have heretofore been carried in the official reports as lepers were, upon microscopical examination, found not to be afflicted with the disease. If this same proportion should hold in the remaining islands of the Philippines the total number of lepers will be much less than has heretofore been thought to have been the case. Many physicians, with considerable experience in the Islands, have always maintained that there were at least ten thousand, but later observation seems to indicate that there are under four thousand. If such should actually prove to be the case it should not be so many years before the leper problem in the Philippine Islands is entirely solved.

Owing to the improved cholera conditions in Manila and vicinity, the outgoing quarantine detention which has heretofore been imposed upon outgoing vessels bound for Philippine ports was removed November 10.

Major Mearns, United States Army, who has been Chief Surgeon of the Department of Mindanao, and who was previously reported as being relieved from duty in the Philippines and proceeding to the United States by the next transport, has decided to remain some time longer in the Islands, and last week went to one of the least explored of the Philippine Islands, viz., the Island of Mindora, for the purpose of pursuing his studies as a naturalist. Mr. Horace Fletcher, the advocate of the so-called "Fletcherism," has accompanied Major Mearns on the trip.

Progress of Medical Science.

New York Medical Journal, December 22, 1906.

Paralysis of the Peroneal Nerve Following Childbirth.—After some observations on the various paralyses following childbirth, J. H. Lloyd gives the history of one case of paralysis of the peroneal or external popliteal nerve. His patient was a woman of twenty-three years, primipara and delivered by forceps. Labor was slow and the pelvic measurements were rather small throughout. The patient did well till the ninth day, when she complained of numbness and tingling in the left leg. It was found that there was paralysis limited to the muscles supplied by the peroneal nerve and of the skin supplied by the same nerve. There was also some pain about the hip and a subjective sense of numbness which the patient said involved the whole limb. The office of the muscles involved being to extend the foot and toes, the result of paralysis was to produce a very characteristic foot drop. The author finds the true explanation of involvement of this particular nerve in the anatomical relations of the lumbar and sacral plexuses. The sacral plexus receives from the lumbar a large nerve trunk called the lumbosacral cord which, passing from above downward into the true pelvis runs over the brim of the pelvis at a point where it may be readily compressed. The great sciatic nerve generally divides into its two terminal trunks just above the back of the knee joint, but it may divide anywhere between the sacral plexus and the lower third of the thigh. In case of a high division the portion of the main nerve going to form the peroneal nerve is really the lumbosacral cord. In fact the former is a continuation of the latter. Hence pressure from the child's head might easily affect the lumbosacral portion and the manifestations of such pressure would be noted in the regions supplied by the peroneal nerve.

Rhinitis in Children Including Recurrent Coryza, due to Intestinal Autointoxication.—After some remarks on the circumstances under which rhinitis occurs in children, L. Fischer describes what he calls intestinal rhinitis, a form caused by the results of indigestion. It occurs frequently in dyspeptic children with residual and intestinal stagnation. The vasomotor nerves supplying the mucosa of the nose when affected by intestinal toxins produce vasomotor disturbances, one of which is recurring coryza. Climatic conditions are naturally a minor factor in such cases. When this form occurs in children the urine invariably contains indican. The peculiar gastric and intestinal disturbance arises from overeating meat. It should be prohibited in every form as soon as any evidences of the rhinitis appear. Saline cathartics should be given, sodium phosphate being administered in sufficient quantities to produce liquid stools and the administration kept up until the urine contains indican. Water should be taken freely and fruit may be given in abundance. Milk, buttermilk, cereals and butter should be prescribed. The author regards it as irrational to use the familiar oil sprays and powders. The proper plan is to seek out the cause of the rhinitis and remove it. We must remember that rhinitis may usher in meningitis, various eruptive fevers, diphtheria, influenza, and specific disease.

Is the Supposed Efficacy of Quinine in Malarial Fever More Apparent Than Real?—A. C. Jacobson says that we know that plasmodia are driven out of the blood stream and kept out as long as sufficient quinine is administered and absorbed. Their disappearance does not mean that they have been destroyed since upon the withdrawal of the quinine they reenter the blood seeking refuge and sustenance, when hard pressed, within the erythrocytes. Hence quinine is at best only a palliative. It is not curative and is in no sense of the word a specific against malaria. It frequently happens with patients whose paroxysms have been relieved by quinine, but who have the plasmodia still remaining in their blood that on the withdrawal of the quinine they again have the paroxysms. Large doses of the remedy may even induce chill and fever. The leucocytes become paralyzed. Kidney damage may result from quinine and it is the author's opinion that the renal damage following artificially induced paroxysms of malaria is of a higher grade than that of the usual kind. Hemolysis must be favored by quinine because of the full sway of the plasmodia in the presence of leucocytic paralysis. This increased hemolysis when coincident with the renal irritation constitutes with the latter the determining factor of hemoglobinuria. The author also declares that the withholding of quinine during acute malarial attacks will expedite ultimate cure. In chronic malarial cachexia the uselessness of the remedy is generally recognized.

The Scope of the Federal Food and Drugs Act.—H. W. Wiley calls attention to the fact that under the new law there are two standards for drugs entering into interstate commerce. First, that of the U. S. Pharmacopœia and second, those placed on the drugs themselves. Drugs used for technical purposes are not included in this category. In case of alcoholic beverages when used as such, it is not necessary to state on the label the quantity of alcohol they contain, but if used as tonics, etc., the label must bear the percentage statement. A legal point comes up here concerning which the author gives no positive opinion. A physician orders wine or malt extract. The patient may buy it at a saloon where it is a beverage or at a druggist's where it is called a remedy. In either case, however, the package should theoretically contain a label stating its alcoholic percentage. The most striking feature of the act is that relating to the practical exemption from supervision as to the standards, of the so-called proprietary remedies. Amendments to the act are needed which shall impose equally rigid inspection upon such proprietery remedies. A large majority of all these preparations are made by firms whose names do not appear on the labels and who would doubtless be ashamed to have them there. As is well known, most of this class of remedies which are of any real therapeutic value are merely old-time prescriptions done up under new names or compounds of some of the newer laboratory products.

Journal of the American Medical Association, December 29, 1906.

Closing Aseptic Abdominal Wounds.—H. O. Marcy emphasizes the importance of accurate readjustment of the severed structures with aseptic buried sutures, and gives details of his methods in abdominal wounds. He considers the reduction of scar tissues to a minimum a very important factor, rejects drainage as a rule, and in dressing the wound, instead of employing dressings for absorption of exudates he uses one for their retention in the form of collodion, in which has been incorporated enough iodoform to make it light-yellowish urine color. He prefers the contractile collodion, as it contracts more firmly and holds the skin better in place. This comes off in about ten days, and he usually uses a second and third application to complete the process.

Diphtheria Bacilli in Meningitis.—J. Morrell and H. E. Wolf report a case of meningitis in a child in whom the diphtheria bacillus, identified morphologically and culturally as well as by inoculation experiments on guinea-pigs, in which it produced typical symptoms, was obtained from the cerebrospinal fluid. The bacillus was found both by antemortem spinal punc-

ture and after death. The authors remark that they have found but one case in the literature, that of Wilson and Head, in which this organism was positively identified from the central nervous system, and think that the circumstances of this case indicate that it occurs more commonly in that location than has been suspected, and that, with careful examination, it will be found more frequently.

Cerebral Palsies of Children.—W. J. Butler discusses the etiology of the spastic cerebral paralyses in children, and reports three cases. He comes to the conclusion that the causes are essentially the same as those that give rise to hemiplegia in later life, and can be stated briefly as follows: First, vascular lesions, viz.: (a) hemorrhage from venous or arterial rupture, the result of trauma occurring spontaneously in intense congestions, as in convulsions, or the spasms of whooping cough; (b) embolism from cardiac or arterial thrombi or endocarditis; (c) endarteritis and thrombosis. Second, inflammatory changes, to-wit: acute encephalitis and meningoencephalitis. Third, rarely, a tumor. In children we lack the miliary aneurysms and arteriosclerosis of later life, but the intense congestions to which they are subject in convulsive diseases are enough to compensate. While the frequency of acute inflammatory processes as a cause may be in dispute, the fact that they may be occasionally causes seems established beyond a doubt.

The Blood in Infantile Bowel Troubles.—J. C. Cook reports the results of examinations of the blood in 30 cases of bowel and other affections of infants, in which the white and red cell counts, differential counts of the white cells, and hemoglobin tests were made. The cases all presented, more or less, the clinical aspect of anemia, and included, besides the intestinal and gastric disorders which constituted the majority, cases of acute infections, chronic disorders, like scurvy, rickets, etc., and also syphilis, cretinism, and cerebral paralysis. From the results it would appear that the value of the blood count in the diagnosis of infantile anemia is comparatively slight. In those cases, however, which present the clinical aspects of anemia and show a higher or even normal blood count, there is a concentration of the blood, indicating a lack of sufficient fluid ingestion or a depletion from vomiting or diarrhea, and probably a high concentration of toxic substances. An examination of the special congenital diseases in the series, as compared with those of so-called enteritis, would suggest that the increase in the number of white cells is probably due to the specific character of absorbed toxins. If there is more than one variety of microorganism in the intestinal and other lesions, the number of white cells and the differential count will not be characteristic of either. We must look to the hemoglobin test for more definite information as regards the condition of the blood in these cases. Taken in conjunction with the red cell count it can be seen that the color index gives the more exact indication of the clinical condition.

Reduplication of Heart Sounds.—From a study of 162 cases, in which were considered all the various conditions that might affect the phenomenon, past and present morbid states, general conditions, relations to exercise, habits, etc., H. C. P. Pillsbury summarizes his results, in substance, as follows: Reduplication of heart sounds is a not uncommon symptom. The cause may be either the asynchronous contraction of the ventricles or the auricular sound. Normal persons with thin chest walls usually show reduplication. Those with thick chest walls should not. In persons who should not show reduplication it is a valuable sign. Reduplication of the first sound means that the heart is not working properly. This may be due to nervous interference, as in persons with bad habits, or it may mean that the heart is hampered by external causes, by pressure or by traction; or it may signify that the heart muscle is inefficient, either from systemic conditions or from inherent defects. Reduplication of both first and second sounds is usually only a more advanced degree of the same condition. Reduplication of the second sound alone means an alteration in the relative blood pressure of the systemic and pulmonary circulations.

Uveal Sarcoma.—Brown Pusey emphasizes the importance of making microscopic sections of the eyeball as soon as possible after its enucleation for uveal sarcoma. He reports a case in which, while the diagnosis of choroidal sarcoma was clear, the enucleated eyeball showed no macroscopic indication of external extension of the growth. Nevertheless a year and a half later a pigmented tumor was removed by exenteration of the orbit. If the sections of the eyeball had been promptly made and examined microscopically at the time of the first operation the later operation might have been avoided.

The Lancet, December 8 and 15, 1906.

Epileptic Idiocy Associated with Tuberose Sclerosis of the Brain.—The patient of Mr. G. Dobson was a boy of ten years, who died from pneumonia. The mother was of a nervous temperament, and the father had a weak chest. The whole family circle was neurotic, and some had died from pulmonary tuberculosis. Convulsions came on one year after birth. Autopsy showed the cortex cerebri covered with large white granular looking and exceedingly hard areas, occupying more especially the fronto-parietal and temporosphenoidal lobes of both hemispheres. These sclerosed areas protruded slightly above the general surface of the brain, and a few showed central umbilication. On section these areas showed considerable cortical hypertrophy; they were white in color, and the normal striations were almost absent. The cortex was badly defined, and tended to pass gradually into the underlying medulla. The transition from normal to sclerosed cortex was sharp. The vessels of the medulla, more especially in the occipital regions, were surrounded by collars of gelatinous-looking material. The lateral ventricles were not dilated. The choroid plexuses were healthy. Under the ependymal lining, which was smooth and glistening, hard, white, nodular growths were seen (varying in size from that of a pin's head to that of a small hazel nut) projecting into the ventricular cavity. These growths occurred in the groove between the caudate nucleus and the optic thalamus, and appeared to run along the course of, and to be intimately connected with, the vein of the corpus striatum. Two very tiny growths appeared on the wall of the third ventricle; the fourth ventricle was healthy. No pathological change was noticed in the cerebellum, pons, or medulla. Red hepatization of both lungs was present. No change of any interest was found in the other organs of the body. The microscope revealed the sclerotic areas as a firm, dense network of fibers quite devoid of cells. The subependymal tumors were covered by a single layer of columnar-shaped epithelial cells. Beneath this healthy ependyma was a firm, dense network of fibers, containing numerous cells. The blood vessels in this layer were fairly numerous, and were contained in dilated perivascular canals. The main growth beneath this layer was composed of coarse connective tissue, the blood-vessels of which had thick, diseased coats, the lumen being in some instances nearly obliterated. In the medulla the vessels were contained in round, wide spaces. Surrounding the vessel wall and occupying this space were found cells having long, delicate intertwining branches. The appearance suggested myxomatous degeneration of the adventitial coat.

Coincident Acute Appendicitis and Twisted Ovarian Pedicle.—J. Cahill and W. H. Bennett report the case of a girl of seventeen years suddenly seized with the usual symptoms of inflammation in the right iliac fossa. Surgical intervention was recommended but refused, and the patient went along for a week, the evidences of inflammatory deposit gradually becoming more and more evident. Abdominal incision was finally made on the seventh day from the initial symptoms. The appendix, which lay posteriorly, intimately matted to the bowel, and surrounding parts by firm adhesions was removed and showed a tight constriction at a quarter of an inch from its junction with the cecum and another towards its distal end. Between these points it was greatly distended with pus, and its wall showed all the conditions of very chronic disease. The extreme distal end was little more than a fibrous cord. No suppuration had occurred outside the appendix itself, but the intestinal coils around were greatly injected and matted by recent adhesions. Upon making the usual further examination of the abdominal cavity a dark firm mass was found occupying the upper part of the pelvis and intimately adherent to the rectum, the uterus, and the bladder. After a considerable extension of the abdominal incision this mass was with very great difficulty separated from the parts with which it was matted and was brought up to the wound. It proved to be an ovarian cyst of about the size of a cocoanut, with a very thick pedicle which had become twisted upon itself for about three quarters of a complete turn. Its walls were thin and blackish and its contents mainly decomposing blood. The pedicle was ligatured in the usual way and the cyst was removed. The operation which was necessarily prolonged, was well borne and the subsequent progress was steady and uneventful.

The Influence of an Excessive Meat Diet on the Osseous System.—The investigations made by D. C. Watson on a large number of meat-fed rats show that the bones of animals fed on an excessive meat diet present an appearance of delayed and imperfect ossification with increased vascularity and an increase in the number of red blood corpuscles. Associated with this there is in a number of cases the presence in the bony ribs of nodules of cartilage,

developed from the periosteum, with direct transformation of these cartilage cells into bone. It is noteworthy that, while the naked eye appearances of the skeleton may closely simulate those present in advanced cases of rickets in the human subject, the microscopic appearances in the epiphyseal lines of the long bones are quite distinct from those present in that disease. The author is able to add the history of the case of a child fed on raw meat juice for six weeks. Under this diet the child, originally anemic, became very pronouncedly so and steadily deteriorated. There was marked physical and mental lethargy, fretfulness on movement and a few purpuric and petechial spots. The general appearance recalled to the author the clinical picture he had frequently noted in young rats, and he formed the opinion that the state of profound anemia and physical and mental lethargy was dependent on an exhaustion of the functions of the bone marrow, thyroid gland, and other structures, consequent on the excessive meat consumption by the mother. The child died in a few days. At the post-mortem examination no trace of tuberculosis was found, nor other recognized cause of marked anemia in children. A partial post-mortem examination only was allowed and was conducted by the consultant who had charge of the case, and who kindly gave the author pieces of tissue for histological examination. The long bones were unduly soft in consistence and it is declared that the histological appearances of the radius of this child were identical in their essential features with those present in the ribs of the rats.

Appendicitis as a Cause of Intussusception.—L. Rawes gives the history of a boy three years of age admitted to hospital with an abnormal swelling and colicky pain. For three months previous he had had attacks of abdominal pain, for six weeks frequent vomiting, and occasionally some shreds of blood in the stools. Under anesthesia a reniform tumor about three inches long was discovered just above and chiefly to the left of the umbilicus. On the second day following, abdominal incision revealed the case to be one of intussusception. It was easily reduced with the exception of the last portion (about one and one-half inches), which was edematous and consisted of the appendix deeply imbedded in a fold in the wall of the cecum firmly bound down by adhesions, and this, it would appear, had formed the apex or head of the intussusceptum. On "freeing" the appendix it was found to be in a chronic inflammatory condition and to have perforated about one inch from its base. Appendicectomy was performed and the abdominal incision was closed. The boy made an uninterrupted recovery.

Cancer of the Male Breast.—The patient of G. E. Peachell was a man of fifty-eight years, admitted to hospital for melancholia, with auditory and visual hallucinations. In the left breast, below and internal to the nipple, there was a small, irregular soft lump, non-adherent to the skin or underlying tissues. Squeezing of the breast caused the exudation from the nipple of a little blood-stained fluid, but there was no glandular enlargement. The growth increased in size and was finally removed. It proved to be a typical scirrhus carcinoma invading the pectoral muscle. The man died eight months later from fatty heart and syncope, but autopsy revealed no secondary deposits.

Sprue Treated by Strawberries.—On the strength of the successful result from this plan of treatment in a case previously reported, M. F. Squire details his experience with a man of twenty-nine years with vomiting, diarrhea, and emaciation. At first the case was considered one of colitis and treatment was carried out with this end in view. Later it was realized that the condition was due to sprue. Under a milk diet his condition rapidly improved, but he was a gluttonous eater and was rebellious against dietetic restrictions. The addition of bread and butter and an egg brought about a relapse. Under various diets and on various drugs he gradually deteriorated. Then the strawberry season came around and he was allowed one pound of berries (gradually increased to three pounds) daily. This was in addition to his regular diet of milk, beeftea, bread and margarine, milk pudding, and an egg. From this time he permanently improved, and by the time the berry season was over he was able to resume ordinary diet and made an uninterrupted recovery. Concerning the action of the berries, the author advances no theories along chemical lines. He says simply that they seemed to supply something to the alimentary canal which enabled it to digest and assimilate the nourishment supplied in the diet.

Some Observations on Paralyses of the Brachial Plexus.—A careful consideration is given this subject by W. B. Warrington and R. Jones, who find the common causes of these palsies to be (excluding invasion of the nerve roots by disease of the meninges and vertebræ and pressure by new growths and aneurysms) (1) indirect violence (Erb's or Klumpke's palsy in adults, or Duchenne's if at birth) and (2) rare cases due to neuritis. They have been able to trace the records of thirty cases with eleven complete recoveries, the percentage of recoveries in traumatic cases being somewhat less. They discuss the nature of the lesions and their pathology, and they pass on to consider the symptoms of loss of function in nervous tissue indepent of cause, and finally the symptoms of complete loss of function. Under the latter heading are mentioned: Alteration in sensation, extent of the muscular paralysis, and the electrical reaction of the muscles involved. Under the heading of clinical guides to the seat of the lesion, they state as follows: (1) Pupillary paralysis results from an intravertebral lesion; (2) paralysis of the rhomboid, serratus magnus, or levator anguli scapulæ indicates a lesion internal to the extravetebral portion, situated in either the intra or intervertebral portion; (3) paralysis of the supra and infraspinati muscles indicates a lesion before the formation of the plexus proper. The white rami for the sympathetic, stimulation of which causes dilatation of the pupil and enlargement of the palpebral fissure, are derived from the first, second, and third dorsal anterior roots, and especially from the second. Hence, though damage to the first root causes characteristic oculopupillary signs, they may not be permanent; the use of cocaine may give some information as to the extent of damage, for if the pupil fails to dilate when a solution of this drug is instilled into the eye it is probable that the lesion has affected the second as well as the first root. As to prognosis unmodified by surgical treatment, they conclude (1) that the condition is a serious one, only from thirty to forty per cent terminating in useful recovery. That birth palsy of any severity less commonly results in good recovery than the corresponding condition in adults. That the cases due to a local neuritis are a good deal more favorable than when injury is the cause. (2) The pathological experience shows that the lesion is in general a severe one caused by laceration, tearing, or tension of nerve tissue, simple pressure being less common. (3) That a complete block of conduction with a corresponding graver prognosis may be diagnosed from (a) a consideration of the extent and kind of anesthesia (Head and Sherren); (b) a study of the electrical reactions, especially with the constant current; but that the presence of the full reaction of degeneration is compatible with complete recovery; and (c) attention to the extent and distribution of the muscular palsy. The order of gravity of prognosis is lesions of the spinal cord, roots, plexus proper, peripheral nerves. (4) That if spontaneous recovery happens, some signs of it are visible within seven months in adult palsy, but that in birth palsy signs of recovery may be delayed for a longer period, but are complete within a year. In birth palsies partial recovery is frequent, leaving the residual paralysis to be treated surgically. The authors hold that if the paralysis has lasted several weeks, there is little chance of complete recovery unless the elongated muscles are relaxed.

British Medical Journal, December 8 and 15, 1906.

Errors of Vision as a Factor in Motor Car Accidents.—C. Clements reports a series of cases of examination of the eyes in those who have experienced motor car collisions. He notes that both eye and nerve strain if at all excessive, as is so often the case with motorists, are always liable to emphasize an error of vision or a deficiency of muscular tone. This tendency is much increased by approaching dusk. Clements utters a word of warning about motor goggles. Goggles with bowed glasses should never be used under any circumstances, and for this reason—though theoretically they are similar to plain glass, practically they are really myopic glasses of varying strength. Hence they may just turn the scale in favor of spasm of accommodation. Flat, glazed goggles should be worn, and, if required, they can be replaced by the requisite correcting lenses, care being taken that the existing goggles are properly centered. No smoked goggles should be worn after sundown, as they are liable to create a false dusk and so increase the existing danger.

Present Views on Diseases of the Joints.—H. Marsh declares that infection of some kind is the one great factor in joint disease. He makes the following classification: 1st, those following wounds or occasionally operations, or occurring in the progress of acute infective osteomyelitis or pyemia; 2d, those met with in the specific fevers, rheumatism, scarlatina, typhoid, influenza, or in dysentery; and 3d, those caused by some such organism as the streptococcus, staphylococcus, or gonococcus, which may produce, how-

ever, various types of symptoms. While the gonococcus generally causes an acute infection, it may set up an inflammation of a low grade of intensity. It seems to be growing on an exhausted soil and dwindling by extinction. It is doubtless present in small numbers and associated with other organisms which enfeeble its effects. Under these conditions the joint effusion is not necessarily great, but there is a slowly increasing swelling of the synovial membrane and a perisynovial tissue. Pain is a minor factor. Stiffness is usually marked and there is the muscular wasting characteristic of chronic arthritis from any cause. In fact the symptoms strongly suggest tuberculosis. The author says that under the influence of environment the gonococcus has been deprived of so much of its virulence and is in such small quantity that the degree of irritation it produces is practically identical with that to which the *B. tuberculosis* gives rise. Several cases of the type above referred to are detailed. The sources of infection may be various. Even a bad tooth or a mere surface abrasion may lead to joint involvement. The primary step and treatment of such cases is to discover and shut off the source of infection. The particular steps to be followed in handling the joints in any given case will depend on the exact bacterial factor in action. Thus in some instances we should open and drain the joints early. In other cases the joints should be kept at rest and the patient live an open-air life. Douches should be employed twice daily as hot as can be borne without blistering. Small blisters are often useful. If the joint is cool and painless but stiff, manipulation should be the first step. Sometimes permanent adhesions may form leading to ankylosis. Force may be employed to rupture a fibrous union if the limb has become fixed in such a position that the heel cannot be brought down.

Sprains and Their Consequences.—W. Bennett divides sprains into three classes: 1st, those involving the soft parts only; 2d, those associated with fracture, and 3d, those with gross nerve injury. He notes that deferred or remote swelling in deep sprain may show itself a long way from the seat of the original injury in consequence of its being caused by the blood tracking along the fascial planes in the lines of least resistance. In all cases of sprain the first thing to determine is whether fracture coexists, and this can be done by radiography. We should next eliminate the existence of gross nerve lesion. If numbness is found and if it persists for more than twelve hours a gross lesion of the nerve branch is pretty certain. In sprains without swelling, the first indication is relief of pain. We should rest the part and exercise pretty firm compression. This having been effected, massage cannot commence too soon. If extravasation of blood is present, we should first stop the bleeding. Rest is the best remedy. Ice applications are practically useless, and in persons with renal lesions may easily cause sloughing. Hot fomentations, however, are often of value. The increase of the immediate swelling having ceased, should the part involved be a joint, firm pressure by means of a porous bandage, firmly and evenly applied for twenty-four hours, followed by massage, gives the best and quickest results. The use of impermeable rubber bandages is unadvisable. For the prevention of adhesions and muscle waste, voluntary movements, massage, and passive movements rank in the order mentioned. Slight voluntary movements cannot be commenced too soon; splints, therefore, should in a general way not be used. The patient should, in fact, from the earliest moment amuse himself by seeing how far the part, if a joint, can be bent without permanent increase of discomfort. Massage should not, except in special circumstances, be delayed for more than twenty-four hours or at the most thirty-six hours after the cessation of increase in the local swelling. Passive movements should follow freely as soon as all heat has left the damaged part. In regard to remote consequences of sprains, the author makes the following tabulation. Preventable consequences are persistent pain, stiffness, muscular wasting, general joint relaxation, and deformities. Unavoidable in certain cases are osteoarthritis, local paresis, and myositis ossificans.

Cancer: Its Treatment by Modern Methods.—In the Bradshaw lecture E. Owen speaks particularly of cancer of the breast, lip, and tongue, and takes up the treatment by starvation and injections. He gives certain statistical results, discusses the conditions of the "Imperial Cancer Research Fund," and shows results obtained by the labors of the committee of the fund as thus far accumulated. He declares that the Doyen method of injection has proven a flat failure and that the *Bacillus neoformans* of the French surgeon produces in animal experimentation only inflammatory and not cancerous deposits. As yet we know of no sure "cure" for cancer, and he regrets the publicity afforded from time to time in newspapers and periodicals to very misleading notices in favor of the numerous so-called cures. He notes that in the course of inoculation experiments upon mice every now and then a mouse which has been infected with cancer gradually triumphs over the disease, and at last gets entirely free from it. The same thing sometimes occurs in the human subject—an undoubtedly malignant deposit steadily growing smaller, and eventually fading away. Unfortunately, this takes place so rarely in the human subject that it is impracticable to hope for it. *But it may happen;* and in cases in which the disease is regarded as inoperable, the surgeon does not lose sight of this possibility. The question arises as to what there was in those mice, or in that happy individual, which enabled the natural forces to vanquish the disease. And as soon as we are able to imitate that process in the laboratories, the cure of cancer will be within our reach. Is it due to some extraordinary property in the colorless blood corpuscles which has, somehow or other, been awakened into activity, so that the cancer cells—which, in the absence of proof of the existence of specific cancer germs, must still be deemed the essence of the disease—are routed and destroyed? In this direction experimenters are already at work, some with drugs administered by the mouth; others with injections of sterile cultures of potent germs; others with animal or vegetable juices, chemical solutions, or emanations of some radium or electricity. The author refers to the work of Bashford and Murray, who made the discovery that by injecting a few drops of blood from a normal mouse into the circulation of a healthy mouse on which they are about to graft a cancer, they can effectually prevent that graft taking root, though blood of a rat or of a guinea pig similarly injected has no such protecting influence on the mouse. If these results be confirmed by other workers, the next thing will be to find out *why* this happens. And if it be conceded that the mere injection of a few drops of healthy blood can prevent the mouse becoming a prey to cancerous infection, the thought comes home that, after all, it may be only some small thing which is needed to check the progress of a cancer by which a human being is infected—it needs but an infinitesimal amount of vaccine lymph to render a whole country proof against the ravages of smallpox. The time is surely ripe for the advent of a Jenner in the world of cancer!

Berliner klinische Wochenschrift, December 3, 1906.

The Transference of Tumors in Dogs by the Sexual Act.—Sticker expresses the opinion that the reason why it has been found impossible to secure the transference of tumors from one animal to another by the contact that takes place when they are kept together in captivity is because any injury which might become the site of an inoculation is usually also the seat of an infection whereby the vitality of the transplanted cells is destroyed. He was able, however, to produce tumors in a number of dogs that he had inoculated with tumor juice squeezed from a sarcoma of the vagina of a bitch. He also reports the occurrence of sarcoma of the penis in two dogs out of seven that were allowed to copulate with a bitch having sarcoma of the vagina. In each of these instances the period of incubation was about three and a half months, and the growth appeared at a spot on the penis corresponding to the position of the vaginal ulceration. The author suggests that the proof that is thus afforded of the possibility of inoculation in this way should be taken into account in passing judgment on the case of cancer *à deux* occurring in husband and wife which have heretofore usually been considered as being the result of coincidence.

A New Cardiac Remedy.—Lewin and Stadelmann jointly contribute a favorable report on a substitute for digitalis in heart disease. The former author has carried out the chemical and pharmacological investigations and the latter has tested it clinically. The remedy in question is obtained from an East African tree, the *Acokanthera*, belonging to the family of the *Apocynacea*, and occurring from Lake Nyassa, northward into Abyssinia and Somali land. Two varieties are recognized, *Acokanthera schimperi* and *Acokanthera deflersii*. From the wood of these trees several toxic principles may be obtained, of which the most active is a crystalline glucoside, oubain. This is highly toxic and in many respects, which are detailed by the authors, appears to resemble digitoxin. Stadelmann's clinical observations were made on twenty-nine cases of heart lesions, and the remedy was usually given in the form of an infusion made from the wood in the strength of about one per cent. and given in tablespoonful doses. The therapeutic effect is analyzed in detail, but appears to be closely allied to that of digitalis. The remedy has the advantages, however, that the wood appears to keep its virtues indefinitely, in contrast to the well-known instability of digitalis leaves, and oubain can be injected hypodermically without causing pain or irritation. While the authors feel very sanguine as to the future of this drug, they consider

that much more experience with it must be gained by careful tests in hospitals and clinics before its use can be permitted in general practice.

Münchener medizinische Wochenschrift, December 4 and 11, 1906.

Packing the Nose in Ozena.—Sondermann states that the ordinary means available for use by patients with ozena in order to remove the crusts, are inadequate and impractical. The commonly used method of irrigation is troublesome and is therefore often omitted by the patient, and in addition it involves danger of infection of the Eustachian tube and middle ear. He proposes the following plan which he says he has found very successful. The patient is provided with a small bag of very delicate rubber tissue, which is affixed to a detachable tube and rubber bulb. The bag is introduced into the nasal passage in the collapsed condition, and is then inflated by means of the bulb. It applies itself closely to all the irregularities of the wall of the nasal space and even reaches into the nasopharyngeal space. The air is prevented from escaping by the use of a pinch cock, and the bulb is detached; at the expiration of five or ten minutes, the air is allowed to escape and the tampon can easily be removed, carrying with it the crust. The apparatus is kept in water and by the time it is to be used again the adhering crusts will have separated from it. The author advises the use of this method twice a day during the first week and later once a day.

The Treatment of External Anthrax.—Lengfellner says that excision is being used less and less frequently in the treatment of external infections with the anthrax bacillus, and that the conservative method is gaining constantly increasing favor. The essentials of this method consist in leaving the pustule absolutely undisturbed, in thoroughly cleansing its surroundings, in applying a nonirritating ointment in order to prevent rubbing of the dressing, and in suspending the injured member, and keeping it absolutely at rest. The underlying principle is not to interfere with the tissues in their struggle against the germs or to do anything that may cause the entry of these into the blood stream. The author reports fifteen cases of anthrax, in which the diagnosis was made miscroscopically and bacteriologically, and which were treated by this method in von Bergmann's clinic with 100 per cent. of recoveries. In about a third of the cases the pustle was situated on the arm, in another third it was on the face, including one case in which the upper eyelid was infected, in one-fifth it was on the neck, and in one-fifth on the hand. The author states that one case is reported in the literature in which a severe infection was cured by the use of a serum, and he is of the opinion that this method offers great possibilities for the future, and should receive more attention than has hitherto been accorded to it

An Autopsy on a Typhoid Bacilli Carrier.—Levy and Kayser believe that they have been able to offer the first positive proof that the gall-bladder can be the nidus of proliferation for the typhoid bacilli in cases of chronic typhoid carriers. The patient on whom the observations in question were made at autopsy was a woman of forty-eight years, who for thirteen years had been a patient in an institution for the insane. In 1903 she went through with an ordinary typhoid infection without complications, and apparently recovered from this completely. Early in October, 1905, on the occasion of a typhoid epidemic in the institution, it was discovered that the stools of this patient contained typhoid bacilli, and in the course of the following year the authors were able to verify this discovery on ten different occasions. On October 11 the patient died of a septic infection, and at the autopsy it was found that the right lung was the seat of a hypostatic pneumonia. Cultures made from the interior of the spleen, the interior of the liver, the wall of the gall-bladder, the bile, and the interior of a gallstone whose exterior had been sterilized by heat, all revealed the presence of typhoid bacilli in these situations. In the authors' opinion this case, particularly the discovery of the bacilli in the interior of the gallstone, affords proof of the view that the gall-bladder is the seat of chronic typhoid infections, and also of the fact that such persons may suffer from an autoinfection, for they regard the patient's death as being the result of a typhoid sepsis as evidenced by the presence of bacilli in the spleen.

A Convenience in Examining Sediments.—Sachs-Muke calls attention to the length of time that is often necessary in examining sediments microscopically, such, for example, as those obtained from supposably tuberculous sputum by means of inoscopy or some other similar process. He then describes a procedure intended to render such examinations less tedious. This consists in spreading out about .5 c.c. of the sediment on the surface of the slide and allowing it to dry. A similar amount of sediment is added and the procedure is repeated, and the process is continued until the necessary quantity of sediment has been transferred to the slide. The preparation may then be stained in the usual way. As the sputum by previous treatment has been rendered free from coarser particles, mucus, etc., the film of sediment adhering to the slide is perfectly well suited to microscopical examination, and in this way a considerable bulk of sediment can be thoroughly searched through in much less time than if a large number of separate preparations were made.

Deutsche medizinische Wochenschrift, December 6 and 13, 1906.

Agglutinins and Specific Immune Bodies in Gonococcus Serum.—Vannod describes the manner in which he was able to obtain a specific agglutinating serum from rabbits that had been treated with an extract of gonococcus cultures. For this purpose the bacteria were treated with potassium hydrate and a precipitate was obtained by the addition of acetic acid. This precipitate when dried formed a powder soluble in sodium solution, and it was this material that was used to inject into the rabbits. In this way a serum was obtained which was strongly agglutinating, both macroscopically and microscopically, for gonococci, but not for staphylococci, streptococci, or typhoid bacilli. Meningococci, on the other hand, were agglutinated by the serum, and meningococcus serum was found to agglutinate gonococci. The author also describes the steps by which he was enabled to prove the existence in the gonococcus serum of specific amboceptors, but that the serum did not contain amboceptors specific for meningococci, and that therefore the demonstration of the specific amboceptors, rather than agglutinative power, affords the best differential diagnostic method

The Catgut Suture in Fracture of the Patella.—Riedel does not believe in the use of silver wire as a suture material in cases of fracture of the patella, and describes a procedure which he considers preferable to the open operation. An incision one cm. in length is made two cm. above the upper fragment of the bone, and through this a suitably curved handled needle is pushed behind the patella and is brought to the surface through the ligamentum patella just below the lower fragment. The point of the needle is cut down upon before it is pushed through the skin in order that the four catgut threads, which are now threaded into its eye, may be more readily drawn through the little incision, behind the patella, and out through the upper wound. The needle is then reinserted in the upper incision, is passed down in front of the bone, and emerges at its former point of exit below the patella. It is again threaded with the same strands of catgut, which are brought out at the upper opening and tied to their other ends. In this way the patella is surrounded by the catgut ligatures, and the two fragments are held firmly in apposition. The knot is a buried one, and each of the two small incisions is closed with a single stitch of catgut. The author recommends this procedure very warmly for recent cases, though he gives warning of the aseptic inflammation which the presence of the catgut may occasion. He cites eight cases of fresh fractures treated in this way with excellent functional results. For old cases of ununited fracture Riedel also recommends suture with catgut, but as in these instances it is necessary to freshen the surfaces of the fragments and to remove any synovial fringes, etc., that may have dropped between them, he employs two lateral longitudinal incisions on either side of the patella in order to secure access to the joint. This is done because he is very much opposed to long incisions in front of the patella or below it on account of the interference with kneeling that scars in these situations are likely to occasion.

Analgesia of the Ulnar Nerve from Pressure and Its Value as a Symptom in Tabes.—Jean Heitz declares that analgesia of the ulnar nerve from pressure is not a special symptom in tabes. This symptom is noted with very great frequency in tabes and is found after the abolition of the reflexes and Argyll's symptom. It is more frequent than anesthesia of the skin of the inner region of the arm. Biernacki's symptom appears very early. It is a useful indication in those cases in which the association of two or three symptoms makes clear the diagnosis in incipient tabes. This holds good in patients showing aortic lesions, and old syphilitic lesions, in whom the nervous system and the aorta are affected at the same time. In patients of this kind determination of ulnar analgesia, especially if it is bilateral, offers one symptom more for the clinching of the diagnosis. *Journal de Clinique Médicale et Chirurgicale*

Book Reviews.

RATIONAL ORGANOTHERAPY WITH REFERENCE TO UROSEMIOLOGY. By Prof. Dr. A. von POEHL, Prof. PRINCE J. von TARCHANOFF, Dr. ALF. von POEHL, Dr. P. WACHS. Translated by Dr. CARL SCHÜLIN, Billings, Mont. Vol. I. Philadelphia: Blakiston's Son & Co., 1906.

In 1878 Schreiner isolated in crystalline form spermin, an organic base found in semen, styling it spermin. The crystals of spermin phosphate had been discovered by Boettcher as far back as 1865. In 1890 von Poehl first prepared the base in the pure state in large amounts and published certain important investigations upon its physiological action. Since then he has been unremitting in his labors in this field of organotherapy. The first volume of this work is devoted to a general outline of organotherapy from the viewpoint of von Poehl and his followers, describing the chemistry of spermin, the physiological action, and the clinical value of this preparation.

Prof. von Poehl supports his brief with a mass of experimental data and quotes a full bibliography of the subject. His work is an amplified and codified collection of the mass of research which has been done in his own particular branch of organotherapy, and he is supported in this by a group of workers whose names appear on the title page, including Prince Tarchanoff, who was the first to study the physiological action of spermin. Poehl and his pupils regard spermin as a catalysant (catalysator is the word they use), which assists in oxidation and promotes metabolism. He maintains that spermin is one of the normal division products of the leucocytes and takes a great share in oxidation, and supports this claim by an elaborate meshwork of scientific data, including chiefly observations on the urine—the osmotic coefficient of this fluid, and other means of studying urinary metabolism.

The book will be accepted with a certain reserve by those who have followed the trend of Professor Poehl's work. It will be remembered that doubts have been expressed as to whether his preparation is actually spermin hydrochloride ($C_5H_{14}N_2HCl$), and his methods have been severely criticised. The controversy is an old one now, however, and receives due consideration in this volume. The translation is, on the whole, good, although many un-English words have been coined, not always with felicity, to reproduce the original expressions. Such silliness as the repeated mention of Dr. G. v. Hirsch as "the Czar's physician" should be discouraged in a scientific work.

A TEXTBOOK OF OBSTETRICS. By BARTON COOKE HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals, etc. Fifth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1906.

HIRST'S Obstetrics is so well and favorably known to the medical public that it is hardly necessary to add anything to this announcement of the appearance of a new edition. In this the author has made a careful revision wherever necessary, "paying particular attention to the recent advances in our information regarding puerperal infection and gestational toxemia, but incorporating in the text only the facts that seem at present clearly established." A comparison with the previous edition, published about three years ago, shows few changes of importance, yet such as have been made are of a character to increase the value of the work as a teaching guide to the student and to the practitioner whose lines are laid in the field of obstetrical practice. The illustrations are good, 767 in number, 40 of which are colored. A sacrifice has been made to them in printing the book on glazed paper, the reflection of which makes the reading of the text a trying task to the eyes. Most of the pictures would have been as clear if paper with a dull finish had been used, and those which called for a special surface might have been printed as inset plates. The reader would have been thereby spared much irritation, and we venture to say the book would have found a much wider circle of readers. Publishers in these days apparently attach an undue importance to the work of the illustrator. Pictures are useful, and often necessary, but the text is, after all, the thing, and the reading of this text should be made as easy as possible instead of, as in so many books, a vexation of eyes and spirit.

ABDOMINAL OPERATIONS. By B. G. A. MOYNIHAN, M.S. (London), F.R.C.S. Leeds. Second Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1906.

THE first edition of this really superb work appeared only a little over a year ago, yet so rapid is progress in this most important surgical field that the author has found it necessary to make a large number of additions to the text and illustrations. In this work Mr. Moynihan treats of those diseases and the operations for their relief which concern the abdominal organs common to the two sexes, and all strictly gynecological subjects are omitted. He also excludes, rather arbitrarily, consideration of those organs, such as the bladder and the kidney, which are partly extraperitoneal, and of hernia. The title might be rather "Intraperitoneal Operations," which would more accurately define the scope of the work. The author has very definite views and does not hesitate to advance them, rejecting, to the point of absolute silence, any consideration of methods or technique which do not meet with his approval. This renders the book of special service to the practising surgeon, but lessens its value as a guide to the recent graduate who cannot afford to pin his faith upon the teachings of any one man, however great an authority he may be. The illustrations are numerous and handsome, but it is a pity that the publishers should have sacrificed the text to them by printing the book on highly glazed paper. The reading of the book, especially by artificial light, is for this reason most trying to the eyes. If half-tone pictures cannot be printed on paper with a dull finish, then the illustration should be drawn and not photographed; the text is the thing, after all, in a book of this sort, and simple diagrams will suffice to illustrate it. The book will perhaps be less "showy," but it will be more useful and more read

ESSAYS ON PASTORAL MEDICINE. By AUSTIN O'MALLEY, M.D., and J. J. WALSH, M.D. New York and Bombay: Longmans, Green & Co., 1906.

THESE essays are addressed to the priesthood of the Roman Catholic Church, but their importance will be appreciated by clergymen of other denominations. The subjects present that part of medicine which concerns a pastor and his flock and those divisions of ethics and moral theology which concern a physician in his practice. Pastoral Medicine sets forth facts and principles whereby the physician himself or his pastor may direct the operator's conscience whenever medicine takes on a moral quality; and it also explains to the pastor, who must often minister to a mind diseased certain medical truths which will soften hard judgments, and other facts which may be indifferent morally, but which assist him in the proper conduct of his work. There is, therefore, an urgent necessity that competent men should fix that shifting and debatable point of ethics and moral theology which includes pastoral medicine. The following are among the many topics treated in these essays: Ectopic gestation; pelvic tumors in pregnancy; abortion, miscarriage, and premature labor; cesarean section and craniotomy; maternal impressions; social medicine; hypnotism, suggestion, and crime; the priest in infectious diseases; infectious diseases in schools; school hygiene; mental diseases and spiritual direction; menstrual diseases; epilepsy and responsibility; venereal diseases and marriage, and social diseases. These scholarly essays by Drs. O'Malley and Walsh are pathfinders and most admirable, and should be read and pondered over by the physician, surgeon, gynecologist, priest, minister, editor, lawyer, patient, teacher, and parent. The volume really fills a long-felt want in medicine and sociology.

DIE TUBERCULOSE. Vom Prof. Dr. G. CORNET. Berlin und Reichenhall. Zweite, vollständig umgearbeitete und im Umfang verdoppelte Auflage. Mit 15 Illustrationen, 1 Karte, und 5 Tafeln in Farbendruck. Wien: Alfred Hölder, 1907.

SOME idea of the scope and thoroughness of this work may be gained from the author's statement that during the seven years that have elapsed since the appearance of the first edition about 13,000 articles on tuberculosis have been published, and that most of these have been consulted by him in the original. In consequence of this enormous amount of material to be incorporated, in its present edition the book has been almost doubled in size and now comprises over 1,400 pages. In its original form the work was recognized as one of the most comprehensive on this subject, and it now undoubtedly stands preeminent among treatises on tuberculosis. It would be a work of supererogation to try to summarize the table of contents, which covers twelve pages, or, indeed, to particularize at all in regard to the subjects discussed, for there is no question connected with the disease as encountered by the internist that is not covered, and the author's authority both as a clinician and as an investigator is so firmly established that no discrimination is possible between his achievements in either direction. Within the present limits of space it is useless to attempt to do more than to call the attention of medical readers to the fact that the work has been revised, and to assure those not already familiar with the first edition that this book undoubtedly represents the most comprehensive single treatise on tuberculosis as a whole that has yet been published. Its value as a work of reference may be inferred from the fact that it contains a classified and indexed bibliography of 9,500 articles by about 8,000 authors.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON DERMATOLOGY.

Stated Meeting, Held October 30, 1906.

DR. A. R. ROBINSON IN THE CHAIR.

Three Cases for Diagnosis.—Dr. CHAS. MALLORY WILLIAMS presented three children, the oldest twelve years of age, of a family of four, several of whom had shown typical lesions of syphilis of the skin and of the bones. For several years they had all shown a similar eruption, occurring principally on the forehead near the nose, and consisting of deeply-scratched papules; sometimes arranged in segments of circles, sometimes scattered irregularly. They had been treated for several years, taking mercury, iodine, and tonics internally, and using protective and antiseptic ointments and pastes locally; often with temporary improvement, but with no permanent benefit. Prolonged observation left a strong impression that the scratching was the cause of the eruption, but its persistence in the same region in all of the children was very curious.

Dr. POLLITZER said that without going into the question he was quite willing to concede that these three patients were syphilitics; but he was confident that the papular lesions on the face and hands had nothing to do with syphilis. As to the nature of the process it would be presumptuous for any one to venture on a diagnosis after a single and rather inadequate examination when the excellent dermatologists who had long had the cases under observation confessed themselves at fault. He would like, however, to venture the suggestion that this family disease characterized by the occurrence of intensely pruritic papules, possibly vesicles, resulting in loss of tissue and scarring, located on the exposed parts of the face and hands, might bear some relation to that group of diseases described under the inept term of summer prurigo.

Dr. WHITEHOUSE saw undoubted stigmata of syphilis in all the children exhibited, but was not familiar enough with their histories to state the exact course of the disease in each case. The obstinate skin lesions which they now manifested upon the head and face, however, he did not regard as syphilitic in any respect. It was a secondary local septic dermatitis such as might occur, and continue unaffected to any appreciable degree by treatment, in subjects exhibiting such a lowered state of nutrition, whether due to syphilis or to some other dyscrasia. General constitutional and hygienic measures looking to improvement in their general tone would, in his opinion, be the only successful means of removing the eruption.

Neurotic Eczema.—Dr. WILLIAMS reported the case of a man 25 years of age, a laborer, whose family and the previous personal history were negative. The patient denied having had syphilis or gonorrhea. He did not use coffee or alcohol, but smoked about three ounces of tobacco a week, and took about three cups of tea daily. His diet was rather low, being chiefly bread, milk, and tea, with very little meat. He began to masturbate at 18 years of age, performing the act two or three times a day, often till the blood came. About a year later he noticed an eruption like the present, which he said appeared first on the back of the right thigh. The self-abuse was continued till two or three years ago, since which time he had had sexual intercourse about once in two weeks. Partial erections were now easily provoked, and mental excitement often caused emissions, even without erection. Nocturnal emissions were common, and seemed to occur regardless of sexual intercourse. Since its first appearance, six years ago, the eruption had never been absent more than a week or two at a time. An outbreak was provoked by any nervous or physical strain—a normal coitus, a nocturnal emission, a day's work in the field—and was sufficiently distressing to incapacitate him, so that he hardly did a full month's work in a whole year. The region most affected was usually the face. He said an attack always began with great swelling and redness, so that sometimes he could hardly see. Soon vesicles appeared which ruptured and exuded, the serum drying to a yellow crust, and the process then gradually declined. He was a man of 167 pounds in weight, of stocky build, and nervous, restless manner; tongue moist and coated, appetite good, bowels regular; pulse 66, regular, good force; the urine amounted to 36 ounces in twenty-four hours, sp. gr. 1.018, acid, total urea 12.4 g., trace of albumin, few hyaline and granular casts, no spermatozoa. The scalp was clean. The skin on the middle of the face and forehead, extending on each side about as far as the external canthus, was red and swollen. The border was irregular, with outlying spots of disease, but still fairly sharp. The affected area was set was small papules and vesicles, many of the latter having ruptured, their secretion drying to a yellow crust. There were many scratch marks. Besides the crusts there were many fine, small scales. The swelling was firm, as from a subacute inflammation, not soft and edematous. The skin of the scrotum was dull red, thickened, harsh, and scaling slightly. On the forearms and thighs were a few scattered red papules, the appearance here being that of a mild dermatitis. The chief interest in this case lay in the coincidence of the appearance of the dermatosis with the development of sexual neurasthenia, and in the close causal relationship between the expenditure of nervous force and the outbreak of an acute attack. The diathesis, the faulty metabolism, the personal idiosyncrasy, or whatever it was that determined this particular cutaneous reaction, was at present beyond our knowledge and control; the exciting cause, on the contrary, was found in the neurotic condition of the patient, and this furnished a good mark for therapeutic attack.

Case of Argyria.—Dr. DAISY M. ORLEMAN ROBINSON reported the case of a woman, 54 years of age, a housework-er, brunette, tall, and quite stout. No history of a cutaneous disease at any time in the family. Patient had suffered from constipation since childhood. She was treated by a physician for a catarrhal condition of her throat four and a half years ago, once every two weeks, for a period of two months, a solution of nitrate of silver in the form of a spray having been applied. She then continued this treatment herself daily until she came under the speaker's observation. An ounce of the solution lasted one month, hence she used about five grains of nitrate of silver every month. She first noticed a discoloration of the skin two years ago, after having used about one hundred and thirty grains of the salt, but could not state where it first appeared. The discoloration at present was general over the entire body, but most marked upon the parts exposed to the light, and was of a bluish-gray shade. That on the lower extremities was lighter in color and might not be recognized if examined independently of the rest of the body. The mucous membrane of the mouth had a decided bluish tinge. The discoloration on the gums was less marked. The vaginal mucous membrane, arms, and rectum were similarly discolored. Blood examination showed little or no change in erythrocytes. There was no leucocytosis, the differential count was: eosinophiles 1 per cent., transitional 1.6 per cent., lymphocytes 30.8 per cent, polynuclear 66.6 per cent. The urine had a specific gravity of 1.020, slight trace of albumin, a few hyaline casts, blood, vaginal epithelium, bacteria, and mucus. The case was shown on account of the comparative infrequency of the disease at the present time, and especially because it had been caused by the topical application of the silver salt to the throat. A portion of the skin from the upper part of the shoulder had been

removed for microscopical study, and a report would be given at another meeting.

Multiple Tumors.—Dr. LAPOWSKI presented a man, 20 years of age, with negative personal and family history. The present disease started eight years ago, when a cherry-sized tumor was noticed in the region of the right axilla. Since that time tumors had appeared on various parts of the body, the last coming several days ago on the abdomen. They were now scattered over the whole body, on the forehead, upper and lower extremities, and trunk. Some were round, from the size of a small pea to that of a bean; others were oblong, from one-half to two inches long. The tumors were under the skin, and both the skin and the tumors were movable. The color of the skin was normal. The tumors were painless, slightly hard, and appeared without any prodromal manifestations. The color of an excised tumor on section was white, of the color of lard; the mass was compact and hard. The glands were not perceptible, the visible mucous membranes were normal, and the general condition of the patient was good. Microscopical examination would determine whether the tumors were fibromata or neurofibromata.

Dr. POLLITZER said he thought the case was one of Recklinghausen's disease—multiple neurofibromata of the skin. The patient's trunk was covered with countless yellow-brown pigmented areas, forming the second symptom in the syndrome of Recklinghausen's disease. The little tumor which he had seen seemed to him to be a neuroma or fibroma, and after an inspection of the case clinically he would say it was probably neurofibroma. He would be pleased to examine the specimen and report on its histopathology at an early meeting.

Tuberculide.—Dr. LAPOWSKI presented a man, 41 years old, of Polish birth, a tailor. Ten years ago he had a pimple of some kind on his penis, which disappeared in a few days. He did not remember any secondary symptoms on either skin or mucous membranes. The present eruption began about fourteen years ago on the face, coming and going, and spreading gradually downward, and had remained practically unchanged for the past eight or ten years. Each lesion began as a pimple with a white center, from which water or matter could be expressed. If not scratched the papules dried and scabbed, the scab later falling, leaving a depressed opening. There was no itching. The eruption was scattered over both lumbar regions and on the flexor surfaces of the upper and the lower limbs, in rings and half rings, which on healing left pea-sized scars, without any pigmentary border on the abdomen, while on the lower extremities there were pigmentary spots. Some had dry blood scabs, on removal of which punched-out bleeding ulcers appeared, not deep or dry enough for a tuberculide. While the man was under observation two months ago, a pea-sized patch developed on the right palm; the epidermis was raised at the edges, the base was slightly scaly. Last month he had an urticarial and impetiginous eruption, which gradually disappeared, leaving the original lesions but little changed. The patient took mixed treatment for a month, and then mercurial inunctions for two weeks, leading to marked improvement in some of his lesions, while the others were quite unaffected. Dr. Lapowski presented also, in connection with this case, the woman shown as a case of tuberculide at the preceding meeting.

Dr. DILLINGHAM did not regard either case as one of tuberculide. The woman he considered as being a case of chronic urticaria; the man had an entirely different disease, and although at first it would suggest syphilis, closer examination showed that the lesions were acute and not characteristic of that disease. It appeared to be a general infection and as there was atrophy it was possible there might be a syphilitic element in it. The speaker would wish to study the case more carefully before making a diagnosis.

Dr. POLLITZER was glad to find himself in accord with the views expressed by most of the speakers as to the nature of these two cases. One of the earliest cases of the disease, now regarded as a type of the tuberculide, to be published with full histological details was the speaker's case of hidradenitis. The evolution and course of that case were perfectly clear in his mind and they were nothing like the case of the woman shown by Dr. Lapowski. The characteristic features of the speaker's case were the origin of the nodules in the deeper layers of the skin, their slow evolution, the breaking down of the epidermis with discharge of pus and necrotic shreds, and the resulting small, depressed cicatrices, the whole without any subjective symptoms. This description agreed perfectly with Barthelemy's account of his acnitis published almost simultaneously and Dubreuilh's subsequent publications. In this case there was nothing of the course of the so-called tuberculide acnéiforme. Here the lesions appeared abruptly on the surface, there was intense pruritus, a papule was formed (as in prurigo), the patient scratched violently, tearing off the epidermis with the nails, a crust resulted, and finally a slight scar. Dr. Pollitzer would call this case one of chronic papular urticaria. As to the tuberculides in general, he desired to place himself on record as not accepting that group of dermatoses as presented by our French colleagues. They were grouping together a number of different diseases virtually on the sole basis of a supposed common etiology which, in the speaker's opinion, did not exist. As to the case of the man, the patient admitted having had a chancre some years ago, and had to-day general adenopathy. He was without doubt syphilitic, and his skin lesions were part of his syphilis.

Dr. WHITEHOUSE regarded the skin affections in these two subjects entirely distinct one from the other, and he considered neither of them examples of so-called tuberculides. The evolution of the lesion in this affection, which he preferred to call necrotic granuloma, was uniform and characteristic in every case that he had seen. It was a deep-seated papule or nodule, developing slowly with slight inflammatory symptoms, the summit of which, after some days, sank in and went on slowly to complete necrosis; upon healing a variola-like scar remained. The man just shown had syphilis, as seen in a circinate patch upon the ankle now about healed and a group of indolent, dull-red papules on the calf of the leg. The eruption on the trunk and limbs elsewhere he considered an independent affection, a folliculitis. He had seen this condition go on for years as the result of an intestinal toxemia. Dr. Whitehouse considered the woman's case to be one of chronic urticaria. The evanescent character of the eruption, including an edematous plaque upon the wrist, the intense itching, pigmentation, and even scars, were all consistent with the diagnosis of chronic urticaria. Pigmentation was not uncommon in this disease nor were scars as the result of local infection due to scratching.

Dr. LAPOWSKI, closing the discussion, agreed that there was a decided element of urticaria.

A Case of Psoriasis of the Scalp and Hands Only.—Dr. A. R. ROBINSON presented this patient, a man, aged 60, cigarmaker, married, five children, seven sisters, and two brothers. No history of any cutaneous disease in the family. Had always been healthy. He was accustomed to eat moderately of a mixed diet, to drink much tea and coffee, and for thirty years had drank two quarts of beer daily. Eruptions first appeared seven years ago, first on the scalp as a small pea-sized lesion; others formed, and by extension and coalescence the entire scalp was affected. Six months after the first appearance on the scalp the lesions appeared on the palm of the left hand, and six weeks later upon the palm of the right hand, and gradually extended to the wrists. The disease had existed continuously since that time, though milder in winter than in summer. The eruption appeared upon the palms as small lesions sometimes increasing in size and uniting to form a patch. Five

years ago small seborrhea-like lesions appeared upon the right side of the nose and upper lip and had remained ever since. No eruption had appeared at any time upon other parts of the body. On the scalp were well-defined areas of psoriasis. Where the hair was absent as on top of the scalp no lesions were present. The case was shown on account of the age at which the psoriasis first appeared and on account of the close similarity of the lesion upon the palms to that of a papulo-squamous syphilide—a resemblance the speaker had noticed before in these cases of atypical psoriasis. A few months ago he exhibited before the New York Dermatological Society an atypical case of psoriasis with very similar lesions upon the palms. In that case the disease was limited to the hands and tongue. This case was atypical on account of the age when the eruption first appeared and the limitation to the scalp and hands.

Case of Atypical Psoriasis of Elbow and One Palm.—Dr. DILLINGHAM presented a case which he said was interesting in that the eruption did not appear until the patient was 45 years of age, and for four years it was confined to the elbows; the case also illustrated that it was often impossible from the palm alone to make a diagnosis between psoriasis, eczema, and syphilis. Jacob S., 49 years of age; no history of venereal disease. Had no eruption until four years ago, when a small lesion appeared on his left elbow, gradually increasing in size, and followed by others, all commencing as small lesions spreading at the periphery. After several months lesions appeared on the right elbow. The eruption had never disappeared, and at no time had there been any serious exudation. A certain amount of itching had been present. A month ago lesions appeared on the left palm without any history of irritation from occupation or otherwise. There had been no eruption on the rest of the body. A diagnosis of psoriasis was made on the character and history of the lesions, the location, manner of spreading, and absence of exudation. Squamous syphilis could be excluded by the location, absence of lesions on the rest of the body, slow growth, and character of the lesions, thickening instead of infiltration in the corium, and absence of atrophy. Eczema could be excluded by the location, character of scales, sharply limited margin, manner of spreading, and absence of serous exudation and of vesicles and papules at the margin. The speaker said he realized that the margin and manner of spreading would not exclude dermatitis seborrhœica, but the reddish color and the elevated and almost tubercular character of some of the lesions would. The age of the patient and the limitation of the disease, although unusual, were not against the diagnosis of psoriasis. Wilson had reported a case of psoriasis appearing for the first time in a patient 85 years of age, and Crocker one at 81 years. In Nielssen's cases 2 per cent. appeared after 50 years of age. In regard to the limitation, Crocker had reported a case in which, although there were two or three attacks, the eruption was present on the palms only, and another case in which it was confined to the left hand for several years and never affected any other part of the body except the right hand earlier. Cavafy had reported a case in which the eruption was limited to the right forearm and hand for twenty years, beginning on the palm. A number of cases had been seen in which the disease was limited to the scalp. When the eruption made its appearance late in life it was more apt to be atypical in character and location.

Two Cases of Syphilis and One Case of Psoriasis of the Palms.—Dr. WILLIAMS reported the following cases:

CASE I.—The patient, a clerk, 30 years of age, applied for treatment February 21, 1906. He had a healed chancre on the penis, a well-marked papular eruption all over the body, and mucous patches in the mouth. The symptoms all disappeared under treatment, which was continued until August. He returned to the dispensary October 3, 1906, with rounded and oval ham-colored spots in both palms, one of them being partially denuded of epithelium in the middle, another just beginning to scale in the middle, others showing only the color and a very slight infiltration.

CASE II.—The patient, a cook, 49 years old, denied having had a chancre. He had two living children, 23 and 21 years old, respectively, and one child, born nineteen years ago, had died. His wife had had no miscarriages. He now had a characteristic tubercular syphilide on both elbows, and syphilitic lesions on the palms, soles, and nails. Some of the lesions on the palms were small, round, very slightly infiltrated, and hardly distinguishable from similar spots on the palms of the accompanying case of psoriasis.

CASE III.—The patient, 55 years old, married thirty-eight years ago, and a widow for twenty-eight years, had had eight children and no miscarriages. Seven of the children died in epidemics. She denied positively having had any eruption until five months ago, when typical psoriatic lesions appeared on the hands and forearms. Some of the lesions on the palms were very suggestive of syphilis, showing the characteristic "collarette," but they were bright red in color instead of dull.

In presenting these cases of eruptions on the palms Dr. Williams called attention particularly to the difficulty in distinguishing certain cases of palmar syphilis from psoriasis on the one hand and eczema on the other. The diagnosis was usually readily made from concomitant lesions elsewhere on the body, or from the history of such lesions, but to decide from an inspection of the palm alone was a different matter. Elliot's sign (the induration or infiltration of the border of a syphilitic eruption), the absence of such infiltration in the other diseases, and Fournier's sign (the sharp limitation of each syphilitic patch as contrasted with the numerous small islands of disease lying near the edge of a larger patch of eczema), were the most useful, but these might fail, and it had been said repeatedly that some cases of syphilis might copy exactly the picture of psoriasis, and others that of eczema. It was in the hope of eliciting further aids in diagnosis that these cases were shown.

SECTION ON DERMATOLOGY

Stated Meeting, Held December 4, 1906.

DR. A. R. ROBINSON IN THE CHAIR

Rhinoscleroma; Marked Improvement Under Radiotherapy.—Dr. W. S. GOTTHEIL presented a woman thirty years of age sent to him by Dr. J. Frankel, July 17, 1905. The growth was said to have begun on the septum five years before, and had been progressing ever since. The central portion of the upper jaw and the septum and alæ of the nose were the seat of a deep and fairly sharply limited infiltration of cartilaginous hardness and absolutely insensitive. The growth evidently involved the bone and cartilage as well as the skin, causing marked protrusion of the upper lip and tilting up the projection of the nose. Both nasal passages were almost entirely occluded, permitting the passage of only the finest probe. The hard and soft palate and the faucial isthmus and posterior pharynx were deformed, thickened, and cartilaginous, and were the seat of chronic ulcerative and cicatricial processes. The general health was fair, though there was some interference with nutrition on account of the interference with deglutition. The larynx was free. The chief subjective complaint being occasioned by the nasal stenosis, attempts were first made at careful dilatation. The most cautious efforts, however, were followed by very profuse and obstinate hemorrhages, one of which was so severe that the patient had to remain several hours at the office with the anterior nares and posterior pharynx tightly plugged before it was safe to send her home. Recourse was then taken to the *x*-ray, and during the past eighteen months the patient had had about fifty sessions at rather irregular

intervals. There was a moderate reaction at various times, during which the patient's subjective difficulties had always been increased; but she always improved when the inflammation subsided. Dr. Gottheil was using the Cornell tube of small size in the mouth and nares. The result had been a marked diminution in size, to the extent of about one-half, in the tumor mass of the upper jaw and nose. The external deformity had been very greatly improved. The pharyngeal ulceration had also gotten better, and swallowing was easier. The nasal stenosis had not yet been affected; but the intranasal treatment had been begun only a short time ago.

Dr. Gottheil, replying to questions, said that he had found radium of no value in these cases. He said he used Cornell *x*-ray tubes, made so small and of such shape that they could be put in the mouth and in the nostril, in contact with the diseased tissue, and he believed that by preventing the passage of the rays through the atmosphere he avoided their irritant effect. He said also that he was a great sceptic as to the value of the *x*-rays, and used them here because he did not know what else to do, the patient bled so alarmingly at the slightest touch.

Syphiloderma Framboesiodes.—Dr. W. S. Gottheil presented this patient, a colored woman, twenty-three years of age, potator, smoker, dissipated. She had been admitted to City Hospital October 15, 1906. There was no venereal history. She had been operated on for cervical adenitis in childhood, and a laparotomy was performed at Johns Hopkins for reasons unknown five years ago, and for the sinus left therefrom an operation was performed one year ago at the Metropolitan of this city. The present skin lesions developed four years ago, and while they had improved at times, she had never been well. Subjective symptoms had been limited to itching, with occasional attacks of soreness. She had been in the City Hospital for her skin affection on three previous occasions for various periods as follows: February 15, 1904, Service of Dr. Bronson, diagnosis, chronic eczema; also had gonorrheal ophthalmia. March 29, 1904, Service of Dr. Fordyce: diagnosis, eczema sicca. April 13, 1905, Service of Dr. Greene: diagnosis, chronic eczema. There is a note on this last record of tertiary syphilis being suspected; but no antiluetic treatment was instituted. She showed the following conditions on admission: Nostrils, left of half of upper and lower lips, and adjacent cheek were covered with impetiginous crusts, under which was an eroded and fissured skin; lesion apparently eczematous. Mucosæ normal. The entire pubic and adjacent regions were covered by a large triangular lesion, the upper base of which started on each side one and a half inches from the iliac crests and extended inwards and upwards toward the umbilicus. The apex of the affected triangle extended downwards along the sides of the labia on to the perineum and thighs, and then upwards to the very extremity of the intergluteal folds; there was also on each side posteriorly a transverse extension of the affected area in each fold between buttock and thigh. The lesion itself formed a continuous moderately hard infiltrated and indurated mass covering the above-described area. Its margins were sharp, elevated, and slightly circinate in places. Its surface was irregular, oozing, and partly covered with crust of exudation and macerated epithelium. Where the folds of the skin were in apposition in the fairly stout patient the surface of the affected area, while slightly hypertrophic, was moist, oozing, and eczematous. The diagnosis at first was eczema marginatum, though the essentially hyperplastic and tuberculous character of the lesions was not usual in this affection. Thorough cleansing and a dusting powder were ordered. Examination of the scales and detritus failed to reveal any hyphomycetic fungi. By October 29 the surfaces were cleansed and the eczematous symptoms had subsided. It then became evident that the lesion was essentially framboesiform; distinct tubercles were visible at the margins, and there were circular depressed areas of scar tissue in various places, especially at the posterior apex of the affected region over the sacrum. Microscopic sections showed no fungi, but a small-celled inflammatory infiltration round the basal capillary vessels and evidences of chronic vascular inflammation. The diagnosis was changed to tertiary syphilis, and the patient put on appropriate treatment. By November 26 the patient had had three ten-minim doses of the ten per cent. mercury salicylate intramuscular injections, and was up to 160 grains of potassium iodide daily, with no local treatment. The improvement was very marked, the surfaces absolutely dry; the tuberous infiltration rapidly disappearing. When shown to the section, only the remains of the eruption were visible.

Dr. Bulkley said that there must have been something more than syphilis in this case to account for the duration and the unusual appearance of the lesions, and called attention to their resemblance to those of blastomycosis.

Dr. Lapowski endorsed the suggestion of blastomycosis, and called attention to the fact that, as this disease improved under the use of potassium iodide, the improvement in this case under mixed treatment was no proof of its syphilitic nature.

Dr. Gottheil admitted the presence of an impetiginous element in the eruption, but did not accept the suggestion of blastomycosis.

A Case of Multiple Chancre.—Dr. Lapowski presented a man thirty years old who had had coitus eight weeks ago, and who at that time had an abrasion on the abdomen a little below the umbilicus. The patient showed when presented three lesions, each about the size of a twenty-five cent piece: one of thirty-five days' duration, at the site of the former abrasion on the abdomen, one of twenty-eight days' duration on the upper surface of the root of the penis, and a third of twenty days' duration on the anterior surface of the pendulous portion of the penis. All the lesions were hard to the touch, especially the one at the root of the penis and that on the abdomen. The lesion on the abdomen was round and sharply defined, the surrounding skin normal. The edges were sloping, the surface smooth, shiny red, and on pressure a serous fluid oozed out. The center was crateriform, with a yellowish-gray adherent membrane. The lesion on the root of the penis had the same characteristics, but it was harder to the touch, and the central part showed scar tissue. The lesion on the pendulous portion was not so hard, and had a narrow border with dry, bloody crusts. The central portion was covered with a detachable membrane, underneath which the surface was red and shiny. On the scrotum was a longitudinal abrasion of one day's standing. On the trunk a macular eruption was developing, which was not visible five hours before. In both inguinal regions were packets of hard, enlarged, painful glands. The mucous membranes were normal. Dr. Lapowski promised to report at the next meeting in regard to the presence or absence of spirochetes.

Case for Diagnosis.—Dr. A. R. Robinson presented a man, aged forty-nine years, a piano-maker by occupation. He had always enjoyed good health except when at the age of seventeen years he was ill for eleven months with "nervous gastric fever." On March 10, 1906, he was admitted to the German Hospital on account of an "eczema" and muscular rheumatism. For the cutaneous eruption chrysarobin was employed. About the beginning of March he noticed a few pimples in the inguinal region on the left side. They all disappeared except one, which continued to increase in size, and on account of which the speaker presented him before the section for diagnosis. The patient stated that at one time the growth became reduced in size to that of a bean. It was situated somewhat to the right of the middle of and above Poupart's ligament. The condition had not changed since he came under Dr. Robinson's observation six weeks ago. The lesion was

about one inch in diameter, sharply limited, elevated about one-quarter of an inch above the general surface, reddish in color, and with an erosive surface covered with a clear mucoserous exudation. There were no signs of ulceration or abscess formation. The lesion was quite firm and resistant on pressure. The clinical characters were very similar to some forms of hard chancre. The exudation showed only leucocytes and staphylococci and liquid exudate. A small portion was excised for microscopical examination. The diagnosis seemed to lie between a lesion from staphylococci or mycosis fungoides. The latter was regarded as not probable, on account of the history of the case. Dr. Robinson promised that the case would be carefully studied and reported upon later.

Dr. WISE said that he had seen this man at the New York Skin and Cancer Hospital about nine months ago. At that time he had a dry, scaly eruption on the scalp, while most of the rest of the body was covered with a moist eczematous eruption, which was believed to be the premycotic stage of mycosis fungoides. There was no tumor in the groin at that time. He saw the patient a week or two later at the German Hospital, where the first diagnosis was severe seborrhoic dermatitis, which was later changed to mycosis fungoides.

Dr. BULKLEY said he believed the case to be one of a very early stage of mycosis fungoides, with beginning ulceration. He thought that other tumors would develop before long.

Lupus Erythematosus Disseminatus.—Dr. L. DUNCAN BULKLEY presented two cases of this disease. The first patient was a woman twenty-five years of age. Her father was living, sixty-eight years of age, but suffering from a chronic cough and progressive loss of strength, following an attack of pneumonia eight years before. The rest of the family were well. The patient was married in September, 1903, and her only child was born in April, 1905, and died three months later of summer complaint. Her husband had been in the King's Park Insane Asylum since April, 1905, and was said to have a red, scaly eruption on his scalp. The patient had scarlatina and measles in childhood, but no other illness until the spring of 1904, when she had an attack of diarrhea with bloody stools, lasting about a week. The blood was bright red, but not clotted. There was a good deal of colicky pain and some tenesmus, but no continuous rectal pain, and no hemorrhoids. She had been subject to diarrhea ever since, especially after catching cold, but the later attacks had never lasted so long, and there had been no bleeding. Piles were first noticed about the time of the birth of her child, in April, 1905, soon after which she went to the King's County Hospital on account of severe steady pain in the lower part of the abdomen and in the pelvis. This was relieved, but returned again in a week or two, and was again relieved by internal medication without local treatment, and had not been felt since. In February, 1905, when seven months pregnant, she first noticed a swelling and redness of the upper lip. There were no papules at that time, not even a scale, and no constitutional symptoms, and after a few weeks the lesion disappeared. In February, 1906, she began to suffer from loss of appetite, languor, weakness, and headaches worse at night. Her hair began to fall, and she had chills, often quite severe, and usually occurring at night. After being sick a month she went to a physician, who she says gave her mercury, and after a week's treatment with him the present eruption developed, coming first on the lip, as it had done the year before, affecting the eyebrows about two weeks later, and spreading thence to the nose and cheeks, and then involving the fingers. There was still only redness and swelling; neither pimples nor scaling. Her general condition grew worse as the eruption developed, and in April she entered the King's County Hospital, having then a temperature of 104°. She said nothing was done for her there, but she improved, and was discharged after a month's stay, and remained in fair condition all summer, though not quite so strong as usual, and with a slight redness of the affected portions of the face and hands. Early in the fall, both constitutional and local symptoms increased again, and then for the first time scaling was noticed, and red pimples with white centers appeared, which on healing left deep pits. When she first came to the Skin and Cancer Hospital on November 14, 1906, she had typical lesions of lupus erythematosus on the eyebrows, cheeks, nose, and lip; and on the fingers red, shiny infiltrated masses, one-eighth to one-half inch across, thinning out toward the periphery, and sometimes beginning to scale in the middle, and occupying the skin itself, rather than forming papules or tubercles. Both the palmar and the dorsal surfaces of the fingers were affected. On the rest of the body the skin was clear. The hair was very thin and the scalp was scaly, with a few small ill-defined atrophic areas, but without typical lesions of lupus erythematosus. The inguinal, axillary, and cervical glands were enlarged, and the right epitrochlear gland was palpable. The breathing over the upper part of the chest behind was slightly roughened and the expiration prolonged, and a few subcrepitant râles were heard just above and internal to the right scapular spine. The abdomen was normal and not tender. While in the hospital the patient had no elevation of temperature. Although the symptoms and physical signs were not definite enough to make a positive diagnosis of latent tuberculosis, they might bear that interpretation. The treatment was a six per cent. lotion of resorcin up to November 24, after which date lotio alba of double strength was used. Internally she took one grain of iodoform three times a day up to November 28, when this was replaced by two drops of nitric acid in glycerine and water three times a day. The improvement had been considerable, the congestion in particular being greatly diminished. The second patient was a married woman thirty-eight years of age. Two of her sisters had died of tuberculosis, her mother and three brothers were living and well, her husband had died as the result of a fall. She had had occasional rheumatic pains in the joints for several years, but could tell of no other sickness until the spring of 1904, when she was in bed for two months with weakness, chilliness, feverishness, and eruption of vesicles around the lower part of one side of the chest, accompanied by a burning pain. The scars left by this eruption, which seems to have been herpes zoster, could still be seen. She said that in the early part of the attack she suffered for a week from diarrhea, with bloody stools and colicky pains. She had been losing flesh and strength ever since. About three months after the onset of the above illness she first noticed a red pimple on the right cheek, and within two months the disease spread to the other cheek, and then over the whole head, causing very great loss of hair. After that there was very little change, either in local or general condition, until May or June of 1906, when she was sick in bed with prostration, headaches, anorexia, vomiting, and feelings of chilliness and feverishness, and of great heat in the face. The eruption on the face grew worse at that time, and scabs appeared. Later the eruption appeared on the backs of the hands, spreading thence to the forearms and arms. When she came to the hospital in July, 1906, she presented a curious mixture of lesions, including a large number of superficial pustular bullæ, while the lesions on the arms and scalp were characteristic. She left the hospital much improved, but two or three weeks later, becoming overheated, she relapsed into the same condition as before, and returned. She had no elevation of temperature while in the hospital. Under treatment with nitric acid internally and soothing preparations externally, she had made marked improvement; still the spread of the disease over the back and chest occurred only a month ago. When she was presented before the section, the hair was very thin over the entire scalp, which was thin and

atrophic, but which showed few distinct scars. Above and behind each ear was a poorly-defined bald spot about two inches in diameter. The skin of the entire face was atrophic, reddened, scaly, with considerable rather dense scar tissue on each cheek, where also there were bloody crusts. Throughout the scar tissue on the face were many fine telangiectases. The atrophy was so marked that the mouth could not be opened wide. This condition extended into the chest and down the back to the lumbar region. On these parts the process seemed to be very superficial, and resembled a seborrheic dermatitis, but there was a considerable development of scar tissue in the older parts, the border was erythematous, and beyond the border were characteristic discoid patches. Over the posterior and external surface of the right arm, and the posterior surface of the right forearm, extending around the radial border to the anterior surface and reaching nearly to the ulnar border of the anterior surface in the middle third, and extending down on to the back of the hand, the skin was red, rough, slightly scaly, crinkly, and hot, and showed the development of scar tissue in places. The redness was more marked toward the border, which was raised, erythematous, limited internally by a line of scales attached by their outer margins, and passing externally into normal skin. There were numerous outlying islets of diseased skin. The left arm, forearm, and hand were similarly but less extensively affected. The right palm showed several erythematous spots, about a quarter to a half an inch in diameter, in the middle of which was a small depression left by the destruction of the superficial epidermis, the color being darker about these depressions. Similar spots of erythema with a darker center but without destruction of epithelium occurred on the left palm. Similar spots occurred on both the palmar and dorsal surfaces of the fingers. The lungs were normal. The cervical glands were enlarged. She had a slight cough, raising a little mucus in the morning, but so slight that she disregarded it.

Dr. Pollitzer said he had never seen so extensive a case of erythematous lupus as that in the older woman, and that while the disease appeared fairly often on the backs of the fingers, he believed the lesions on the palms to be unique.

Dr. Gottheil agreed with Dr. Pollitzer. He had never seen erythematous lupus upon the palms, and could not recall ever having seen a report of such a case. He felt very hopeless about the treatment. In the great majority of cases that are cured the lesions must be replaced by scar tissue, and he therefore applied trichloracetic acid or some similar caustic at once, in order to cause destruction of the diseased tissue.

Dr. Dillingham said that in certain superficial forms, like that on the older woman's back, the diagnosis from eczema might be very difficult.

Dr. Williams said that the dense scar tissue on the older woman's cheeks and a few of the small nodules were very suggestive of lupus vulgaris, while some of the papules on the younger woman were suggestive of acnitis, and called attention to the relation of these facts to the theory of the tuberculous origin of lupus erythematous.

Dr. Bulkley, closing the discussion, said that he believed that the great loss of hair in both cases was due, in part at least, to a coincident seborrheic dermatitis, which he believed accounted also for part of the eruption on the older woman's back. Both patients were being treated with nitric acid internally, and both showed marked improvement, though the treatment was purely empirical.

Tuberculosis of the Tongue.—Dr. Lapowski presented this patient, who had been shown before the Section on October 2. Since that time he had given him injections of calomel and of salicylate of mercury, and the improvement in the tongue had been very great indeed.

Dr. Lapowski also reported that the woman shown at the same meeting as a case of tuberculide had received two injections of tuberculin, but that she had shown no reaction to it. The man shown at the meeting of October 30 as a case of tuberculide had received injections of calomel and of salicylate of mercury, and he had improved, but after the injections a few new papules had appeared.

Dr. Pollitzer reported that he had examined sections from the case of multiple tumors in the skin shown by Dr. Lapowski at the preceding meeting, and that they were typical of neurofibroma.

Chicago Medical Society.

At a meeting held November 28, 1906, Dr. Arthur R. Elliott read a paper entitled "Clinical Observations on Blood Pressure in Arteriosclerosis and Bright's Disease, with Suggestions Regarding the Therapeutic Control of Persistent High Blood Pressure," in which he stated that after making due allowance for physiological variations the normal limits of the blood pressure range was from 105 mm. to 140 mm. of mercury. He reported observations on thirty cases of typical advanced arteriosclerosis. The average age of the patients was sixty-one years, and the average maximum systolic blood pressure 148 mm. In fourteen cases (47 per cent.) the blood pressure fell within the normal range. In sixteen cases (43 per cent.) it was persistently above normal, and in six of these latter there was positive hypertension (over 170 mm.), each case displaying evidence of aortic atheroma. The points brought out by his observation in arteriosclerosis were the frequency with which it is not attended by elevation of blood pressure, and the necessity for using the sphygmomanometer in all cases to determine this point, owing to the impossibility of detecting high blood pressure in sclerotic vessels by the unaided finger. The writer called attention to the frequency of chronic nephritis in arteriosclerosis, and the necessity for carefully excluding this factor in high-tension cases. He referred to the researches of Hasenfeld and Hirsch as to the relative involvement of the abdominal arteries and aorta in cases with and without tension, and concluded his consideration of arteriosclerosis with the statement that in any given case of arteriosclerosis the degree of involvement of the superficial vessels is no criterion of the severity of the vascular disease, and that in cases marked with high tension, where chronic nephritis can be proved not to exist, arteriosclerosis of the splanchnic area or of the aorta above the diaphragm is to be suspected. Dr. Elliott also reported blood pressure observations in 60 cases of chronic Bright's disease, as follows: Males, 34; females, 26; average age, 51 years; average weight, 160 pounds; average maximum systolic blood pressure, 190 mm.; maximum recorded in series, 285 mm.; minimum in any case, 110 mm. The essayist reviewed the investigation somewhat in detail, showing that no constant ratio existed between the height of the blood pressure and the amount of albuminuria, the highest average systolic pressure being observed in cases without albumin in the urine. No definite relationship exists between the amount of urine and the height of the blood pressure, a pressure of 285 mm. coinciding with 1,000 c.c. of urine, and, on the other hand, low pressure being observed with a copious polyuria. Attention was directed to the diagnostic value of high pressure reading in nephritis. A pressure of 200 mm. or over should awaken suspicion of nephritis, and necessitate the elimination of this factor beyond doubt before any other diagnosis is accepted. The essayist then proceeded to discuss the management of high pressure cases. He reviewed the pathogenesis of hypertension, pointing out the secondary nature of this symptom and its dependence on systemic toxemia. Reference was made to the greater degree of comfort enjoyed by the nephritic with high tension than by the patient with Bright's disease who had low tension. Inasmuch as the cardiovascular sequence was a reaction against toxemia, he regarded it as

a compensatory, and, from the physiological viewpoint, to some extent a conservative process. Owing to the liability of hypertension to cause serious and often fatal developments, such as apoplexy, cardiac failure, etc., it often requires regulation. The basis of all true procedure in this direction lies in reducing toxemia by regulation of the patient's diet, fluid intake, hygiene, etc., and the main dependence is to be placed on these measures. Increasing tendency is apparent to administer vasodilators for the reduction of excessive blood pressure. This the essayist takes exception to, and advises the utmost caution in procedure along this line. Reduction by drugs is occasionally rendered imperative by serious symptoms, such as angina pectoris, apoplexy prodromes, etc., and under such conditions nitrites, etc., may be freely administered for their temporary effects. As a routine procedure for the regulation of hypertension, vasodilators are seldom justifiable, and when employed should be very cautiously and slowly introduced, watching meanwhile the pulse rate and subjective comfort of the patient as indications of good effect, rather than the degree of reduction in the blood pressure record. The best results are evidenced by a reduction and steadying of the pulse and an increase in the bodily comfort of the patient. A marked fall in blood pressure, which is more than temporary, following the institution of vasodilator medication, is apt to have an unfavorable significance, as it implies a weak heart. The essayist strongly urges greater care and discrimination in the use of medicinal vasodilators in high-tension cases

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MANUEL D' HISTOLOGIE PATHOLOGIQUE. 8vo, 1171 pages, illustrated, paper. Felix Alcon, Editeur. Paris.

THE TREATMENT OF DISEASES OF THE DIGESTIVE SYSTEM. By ROBERT SAUNDBY, M.D., M.Sc., LL.D., F.R.C.P. 12mo, 133 pages. J. B. Lippincott Company, Philadelphia.

KLINIK FUR PSYCHISCHE UND NERVÖSE KRANKHEITEN. HERAUSGEGEBEN VON ROBERT SOMMER. I Band, 4 Heft. Verlag von Carl Marhold, Halle a. s.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

KANSAS STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

October 9, 1906.

ANATOMY AND HISTOLOGY.

1. Locate the brachial plexus and its branches, naming the latter.
2. Describe the medulla oblongata.
3. Locate and describe a femoral hernia and name its coverings, beginning with the surface.
4. Describe the intestinal tract and name its divisions.
5. Locate and describe the omentum, giving the histology of the same.
6. Describe the vulvulæ conniventes.
7. Locate and describe the pancreas, giving its histology.
8. Give the histology of the arteries. Does it differ from the histology of the veins? If so, how?
9. Describe the sympathetic nerve, naming its divisions, and number of ganglia in each.
10. How many bones are there in the human skeleton?

CHEMISTRY AND TOXICOLOGY.

1. What is galvanism?
2. How can it be demonstrated that hydrogen is lighter than air?
3. What is analysis and what is synthesis?
4. What is the effect of inhaling air rich with ozone on the respiratory organs?
5. In what manner does arsenic prove poisonous?
6. How does CO act as a poison?
7. What is the action of KOH on the tissues?
8. What is the antidote for acute poisoning by $HgCl_2$?
9. What is the reaction of blood during gout?
10. What is Trommer's test for sugar in urine?

OBSTETRICS.

1. Write a page on deformities of the pelvis.
2. What would you do in a case of postpartum hemorrhage?
3. How would you treat a case of hour-glass contraction?
4. Write a page on puerperal eclampsia.
5. How would you treat a case of pelvic cellulitis?
6. Into how many stages is labor divided?
7. How would you treat a case of face presentation?
8. How would you treat a case of adherent membranes?
9. Write a page on the use of the forceps.
10. How would you treat fibroid tumors of the uterus?

PATHOLOGY.

1. Define gangrene.
2. What is a sarcomatous tumor? Give its pathology.
3. Define chronic gastritis and give its pathology.
4. Give symptoms, etiology, pathology, diagnosis and prognosis of herpes zoster.
5. Give symptoms, etiology, and prognosis of erysipelas.
6. Give etiology, symptoms, diagnosis, and prognosis of neuritis (multiple).
7. Define lithemia.
8. Define purpura hæmorrhagica.
9. Give differential diagnosis of septicemia and pyemia.
10. Describe the pathology of rachitis.

BACTERIOLOGY.

1. How do bacteria multiply?
2. What is essential to the life of bacteria?
3. Name and describe the malarial parasites.
4. What disease does the bite of an infected *Stegomyia fasciata* produce?
5. Name five culture media.
6. Name and describe the pus-producing germs.
7. Describe Widal's test for typhoid fever.
8. What are leucocytes, and what occurs when they come in contact with pathogenic bacteria?
9. What are ptomaines and toxins?
10. What are sterilization, antiseptics, disinfectants, and germicides?

PHYSIOLOGY.

1. What are the functions of the spinal cord?
2. What is the origin of urea and of uric acid?
3. (a) Describe the vasomotor nervous system and explain its functions. (b) Where is the vasomotor center located?
4. (a) Give the function of the suprarenal glands. (b) What is result of their extirpation?
5. What kind of membrane lines the mastoid cells, and why?
6. Explain the portal circulation.
7. (a) What are the functions of bile? (b) Give its constituents.
8. Describe the pleuræ, giving kind of tissue and functions.
9. (a) Give functions of the cerebellum. (b) What is the result of its extirpation?
10. Give the functions of the medulla oblongata. (a) Name the "centers" located in the bulb.

SURGERY.

1. What class of patients take ether better than chloroform, and why? What class take chloroform better, and why?
2. What are the signals of danger in general anesthesia?
3. How would you treat a suppurating cavity of the thorax?
4. What is the proper surgical treatment of a chronic varicose ulcer of the leg? Give details.
5. What is osteoplasty, and in what part of the body is it most frequently called for? Give an example.
6. Give the cause and treatment of *painful* cicatrix, *adherent* cicatrix, *contracted* cicatrix, and *exuberant* cicatrix.
7. What kinds of tumors are most safely removed? What kinds are the least safely removed?
8. How would you treat an ingrowing toenail? Give full details.
9. What is the best surgical treatment for hemorrhoids? Give details.
10. What bone in the body is frequently fractured and is the most difficult of all bones to reunite by bony union? How should it be treated when fractured? Give details.

OPHTHALMOLOGY, OTOLOGY, RHINOLOGY, AND MEDICAL JURISPRUDENCE.

1. Name some causes of ozena.
2. Discuss the pathological characteristics of nasopharyngeal adenoids.
3. Define strabismus. What causes it?
4. Describe the crystalline lens and give its relations.
5. The vast majority of all the diseases of the ear have their origin in inflammations of what particular membrane?
6. Prescribe for chronic case of otitis media purulenta.
7. Nasal polypi—give diagnosis and surgical treatment.
8. What do you understood by medical jurisprudence?
9. What constitutes a dying statement, and what conditions are necessary to make it admissible as evidence in a court of justice?
10. Give diagnostic symptoms between diphtheria and follicular tonsillitis.

THEORY AND PRACTICE.

1. Write a page on epidemics.
2. Write a page on the treatment of typhoid fever.
3. Give diagnosis and treatment of scarlet fever.
4. Give treatment of erysipelas.
5. Give diagnosis and treatment of rickets.
6. Give diagnosis and treatment of acute laryngitis.
7. Write a page on pneumonia.
8. Describe the different murmurs of the heart and tell what they indicate.
9. Give treatment for acute peritonitis.
10. Write a page on Bright's disease.

MATERIA MEDICA.

1. In what disease is opium used principally?
2. Name the excitomotors.
3. What are the preparations and doses of conium?
4. Is ether ever used as a cardiac stimulant?
5. How should poisoning by digitalis be treated?
6. What are the medicinal uses of ipecac?
7. What substances are incompatible with belladonna?
8. What are the effects, uses, and doses of calcium chloride?
9. What are the preparations and doses of gold salts?
10. Name the mineral tonics.

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

Kansas State Board of Medical Registration and Examination.

October 9, 1906.

CHEMISTRY AND TOXICOLOGY.

1. By the term Galvanism is meant current electricity derived from chemical action, in opposition to that produced by heat or induction. The term is no longer used scientifically; but is laxly employed to denote the constant current as distinguished from the induced current (which is sometimes called Faradism or Faradization).

2. Soap-bubbles or a toy balloon, if filled with hydrogen gas, will rise rapidly in the air.

3. *Analysis* is the splitting up of a compound into its elements or into simpler compounds. *Synthesis* is the building up of a compound from elements or from simpler compounds.

4. It causes severe coryza and hemoptysis.

5. By the ingestion of flypaper, or the water in which it has been placed, poisoning by *elementary arsenic* may be caused. By the inhalation of hydrogen made from zinc and sulphuric acid containing arsenic, poisoning by *Arsin* may be produced. *Arsenic trioxide* can cause poisoning by being absorbed from the mouth, stomach, rectum, vagina, or urethra; or by absorption from the skin in the use of parasiticides or cancer cures containing arsenic; also by inhalation of dust from wallpapers containing arsenic; from clothes dyed with arsenic; and by the ingestion of rat poisons, etc.

6. By uniting with the hemoglobin of the blood and forming a more stable compound than oxyhemoglobin. In this way the power of the red corpuscles to carry oxygen from the air to the tissues is destroyed; and asphyxia is thus produced.

7. It acts as a caustic on living tissues; and disintegrates all tissues, whether dead or alive.

8. White of egg, in not too large a quantity, and followed by an emetic.

9. Alkaline; but the degree of alkalinity may be lowered, and uric acid crystals may be found in the blood.

10. Place in a test tube some urine free from albumin; add a few drops of a solution of cupric sulphate, and then some liquor potassæ (about half as much as the urine); shake and boil. A yellow or red precipitate is formed in the presence of sugar.

OBSTETRICS.

3. First, give a hypodermic of morphine and atropine, or a dose of chloral or an anesthetic, and then, with one hand in the vagina, gently introduce the index and middle fingers into the uterus and through the constricting band. After a time the resistance of the constriction will be thus overcome. By pressing the uterus downward, the fingers and the border of the placenta are brought in contact. Effort is then made to bring part of the placental mass through the constriction; the placenta being removed as in case of adherent placenta.

5. The vagina should be made as aseptic as possible, by means of vaginal douches of bichloride of mercury 1:2,000. The vaginal vault and the cervix uteri can then be painted with tincture of iodine; sometimes the insertion of a vaginal suppository containing about thirty grains of iodoform is of benefit. In case suppuration occurs, the abscess should be opened; if it bursts into the rectum or vagina, measures must be instituted for drainage and disinfection. Very frequently an abdominal operation is necessary. Antipyretics should be given for the fever; and for the pain cold compresses or ice bags should be applied to the perineum and lower part of the abdomen.

7. If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backwards. Spontaneous version may occur, and the presentation become a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations, the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

PATHOLOGY.

1. Gangrene is the complete and permanent loss of vitality in a considerable area of tissue.

2. A sarcomatous tumor is one arising from connective tissue, with excessive cell formation and very little intercellular substance. The cells are either embryonic or imperfectly developed connective tissue cells. Sarcomata are always mesoblastic in origin; their blood supply is abundant, and it is through this channel that they are disseminated; of their lymphatics and nerve supply nothing is known. In gross appearance sarcomata are of a more or less homogeneous nature, the color depending upon the quantity of blood present; occasionally a milky fluid can be expressed, but there is never anything corresponding to the "cancer-juice" of carcinomata. Sarcomata may undergo various secondary changes, such as fatty degeneration, hemorrhages, and mucoid softening. Sarcomata are malignant, hence they have a tendency to spread to distant organs (metastasis), are heterologous, have no definite limiting capsule, tend to infiltrate the surrounding tissues, tend to recur after removal, and cause cachexia and death. They have been classified in a variety of ways: (1) according to the *cells*, as round cell sarcoma, spindle cell sarcoma, giant cell sarcoma, mixed cell sarcoma; (2) according to the *stroma*, as fibrosarcoma, myxosarcoma, chondrosarcoma, osteosarcoma; and (3) according to *secondary changes*, as melanosarcoma, liposarcoma, chloroma.

7. Lithemia is a condition due to imperfect metabolism, and is characterized by an accumulation of uric acid or urates in the blood. It differs from gout in the absence of joint involvement.

8. Purpura Hæmorrhagica is a disease of unknown origin, and is characterized by hemorrhages into the skin and mucous and serous membranes, and usually runs a rapid and fatal course.

9. *Septicemia* begins with a rigor, followed by a rise of temperature up to about 104° F., which remains constant. The pulse is weak and progressively rapid; there is anorexia and constipation, which is followed by diarrhea; the urine contains albumin; the temperature may become subnormal. There are no repeated rigors and no secondary (metastatic) abscesses. *Pyemia* begins with a rigor, which may last for half an hour, and is repeated every one or two days. The temperature rises as in septicemia, but rapidly falls, and at the same time the patient suffers a profuse perspiration. The pulse is weak and rapid; there is anorexia; and there may be delirium, with jaundice and signs of abscesses in the lungs, joints, etc. In pyemia there are repeated rigors and secondary abscesses.

BACTERIOLOGY.

1. Bacteria multiply by fission and by sporulation.

2. Most bacteria require (1) proper temperature, generally at or near that of the body; (2) oxygen is generally needed, those that cannot live without it being called aërobic, and those that can grow without it, anaërobic; nutriment of a proper kind, containing both organic and inorganic material; a slight degree of moisture; a medium of slightly alkaline reaction; and rest. Individual bacteria may require modifications of the above essentials.

4. Yellow fever.

5. Gelatin, agar, potato, bouillon, and blood-serum.

6. The pus-producing bacteria are: staphylococcus pyogenes aureus, staphylococcus pyogenes albus, staphylococcus pyogenes citreus, staphylococcus cereus aureus, staphylococcus cereus albus, staphylococcus cereus flavus; streptococcus pyogenes; micrococcus tetragenus, micrococcus pyogenes tenuis; gonococcus; pneumococcus; bacillus pyocyaneus, bacillus typhosus, and bacillus tuberculosis.

8. Leucocytes are white blood corpuscles. When they come in contact with pathogenic bacteria, if the conditions are favorable, they devour and destroy the bacteria (phagocytosis); sometimes, however, the bacteria manage to destroy the leucocytes.

9. *Ptomaines* are the putrefactive products of dead animal tissues or fluids.

Toxins are the products of pathogenic bacteria or of ptomaines or leucomaines, and are actively poisonous.

10. *Sterilization* is the process of freeing a substance from the live bacteria that may be on it or in it.

Antiseptics are agents which prevent or restrain putrefaction.

Disinfectants are agents which restrain infectious diseases by destroying or removing their specific poisons.

Germicides are agents which destroy bacteria and their germs.

PHYSIOLOGY.

1. The functions of the spinal cord are: (1) the conduction of nerve impulses; (2) reflex action; (3) coordination; it also contains special centers which preside over definite functions.

2. *Urea* is derived from the nitrogenous food ingested; it is manufactured by the cells of the liver.

Uric acid: "In man uric acid has a twofold origin; one portion, coming from the breaking down of the nuclein-containing tissues or cell elements of the man's own body, and hence is of endogenous origin, while the other portion —usually the larger—is of exogenous origin, coming from the transformation of free and combined purin compounds present in the food." (Chittenden.)

3. The vasomotor nervous system consists of (1) a vasomotor center in the bulb, (2) of some subsidiary centers in the spinal cord, and (3) of vasomotor nerves, which are of two kinds: (*a*) those causing constriction of the vessels, and so-called vasoconstrictor nerves; and (*b*) those causing dilatation of the vessels, and so-called vasodilator nerves. These nerves supply the muscle tissue in the walls of the blood-vessels and regulate their caliber, thus influencing the *quantity* of blood supplied to a part; at the same time they regulate the *quality* of blood supplied to a part; they also regulate the *nutrition* of a part, also *secretion* and *heat production*. They are concerned, too, in the control of the heart-beat. The center is in the medulla, in the floor of the fourth ventricle, near the calamus scriptorius.

4. The function of the suprarenal glands is unknown; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body. Removal of these glands is rapidly followed by death.

5. The mastoid cells are lined by epithelium, continuous with that of the tympanic cavity.

7. The functions of the bile are: (1) to assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The constituents of the bile may be shown in the following table, which presents the averages of three analyses given by Hammarsten; the results are given in parts per thousand:

Water	971.380
Solids	28.620
Mucin and pigments	4.910
Bile salts	12.107
Taurocholate	2.431
Glycocholate	9.766
Fatty acids from soaps	1.200
Cholesterin	1.243
Lecithin and fats	0.970
Soluble salts	7.360
Insoluble salts	0.317

9. The functions of the cerebellum are: (1) coordination, (2) equilibrium. Removal of the cerebellum causes loss of these functions.

10. The functions of the medulla are: (1) Conduction of nerve impulses and impressions, (2) as an independent reflex center.

The "centers" located in the bulb are: (1) center for mastication, (2) for secretion of saliva, (3) for sucking, (4) for deglutition, (5) for vomiting, (6) for voice, (7) center for expression (8) cardiac centers, (9) respiratory centers, (10) vasomotor centers.

SURGERY.

2. The danger signals are: (1) lividity or extreme pallor of the face, (2) feeble, irregular, or intermittent pulse , (3) slow and shallow respiration, (4) dilatation of the pupils during deep narcosis.

5. By osteoplasty is meant the transplantation of bone (with periosteum). It is most frequently performed on the skull.

6. *Painful cicatrix* is caused by the pressure of a contracting cicatrix upon the cut end of a nerve or by the inclusion of a nerve in the scar of an amputation stump. In the former case the painful part should be excised; in the latter the stump must be opened and the end of the affected nerve removed.

Adherent cicatrix is caused by simultaneous injury (such as burns or scalds) to contiguous and approximated parts, such as the fingers, or the pinna and the side of the head. A plastic operation is indicated.

Contracted cicatrix is most apt to occur in the flexure of a joint; a serious burn of the hand may cause flexion-contracture of the fingers. The treatment is to divide the cicatrix, dissect out the scar, and follow with skin-grafting.

Exuberant cicatrix consists of a hyperplasia of scar tissue, it is most often found in tuberculous patients, and is of unknown etiology. Excision is useless, as it is very apt to recur. Sometimes it disappears spontaneously.

10. The patella. It is best treated by open operation and wiring.

OPHTHALMOLOGY, OTOLOGY, RHINOLOGY, AND MEDICAL JURISPRUDENCE.

1. (1) Atrophic nasal catarrh, due to syphilis, glanders, caries, or necrosis of the nasal bones; (2) ulcers of a syphilitic, lupoid, or tuberculous origin; (3) foreign bodies and new growths in the nose or nasopharynx.

2. Adenoids consist of lymphoid tissue, which is composed of masses of round cells held together by connective tissue. Mucous glands may be found in the deeper parts of the lymphoid tissue; and the whole is covered with ciliated columnar epithelium.

3. Strabismus, or squint, is a condition in which the lines of sight of the two eyes are not directed towards the same object of vision.

The *causes* are: (1) disturbances of equilibrium of the ocular muscles; (2) errors of refraction; (3) opacities in the cornea or lens; (4) intraocular disease.

5. The membrana tympani.

6. R. Acidi borici ..... gr. xxx
Zinci sulphatis ..... gr. xvj
Glycerin ..... ʒij
Aquæ destillatæ ..... ʒij. M.

Sig. A few drops to be instilled into the ear several times a day.

8. Medical jurisprudence is the application of the knowledge of any of the branches of medicine to the problems and requirements of the law.

9. Any statement made by a dying person who believes that he cannot recover and that he is, at that very time, in actual danger of death. The statement need not be sworn to; it should be voluntary and sincere; and it is admissible as evidence in a court if the individual dies.

10. In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Löffler bacilli may be found.

In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Löffler are not found.

THEORY AND PRACTICE.

8. (1) A systolic murmur, soft and blowing, heard best at the apex, and transmitted to the left axilla and toward the angle of the left scapula, indicates mitral regurgitation. (2) A presystolic murmur, harsh and rough, heard best very near the apex, and not transmitted, denotes mitral stenosis. (3) A diastolic murmur, soft, heard best in the second right intercostal space, and transmitted down the sternum or toward the apex, denotes aortic regurgitation. (4) A systolic murmur, harsh, heard best in the second right intercostal space, and transmitted into the carotids, denotes aortic stenosis. (5) A systolic murmur, heard best over the lower end of the sternum, denotes tricuspid regurgitation. (6) A presystolic murmur, heard best over the ensiform cartilage, and not transmitted, denotes tricuspid stenosis. (7) A diastolic murmur, heard best in the second left intercostal space, denotes pulmonary regurgitation. (8) A systolic murmur, heard best in the second left intercostal space, and not transmitted to the large vessels of the neck, denotes pulmonary stenosis. (9) A murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a hemic or functional murmur, and denotes as a rule an impoverished condition of the blood.

MATERIA MEDICA.

1. In diabetes; particularly diabetes mellitus.

2. Nux vomica and ignatia (and their alkaloids strychnine and brucine), thebaine, ammonia, ether, chloroform, opium, ergot, alcohol in small doses.

3. Conium, three grains; fluid extract of conium, three minims.

4. Yes; on account of the rapidity of its action, ether is a very valuable cardiac stimulant.

5. The patient must be kept in the recumbent position; the stomach should be washed out with infusion of tea; give stimulants and keep the patient warm; tannic acid may be given, as the chemical antidote; and tincture of aconite, as the physiological antidote.

6. Ipecac is used externally as an antiseptic, in cases of anthrax. Internally as a stomachic, an expectorant, an emetic, a diaphoretic, and a cholagogue. It is given in cases of dyspepsia, dysentery, bronchitis, asthma, croup, and in the vomiting of pregnancy.

7. The caustic alkalies are incompatible with belladonna.

8. It is an irritant; applied externally it hastens the coagulation of the blood and makes a firmer clot. It is used

in cases of gastric catarrh and fermentative dyspepsia, in hematemesis and hemoptysis, in glandular swellings of tuberculous patients. It has also been employed in the treatment of pneumonia and phthisis. The dose is seven and a half grains.

9. Auri et sodii chloridum is the only official gold salt; dose, one-tenth of a grain.

10. Iron, manganese, arsenic, bismuth, and phosphorus.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	Feb	1-6
Arizona*	Ancil Martin, Phoenix	Phoenix	January	7

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Pennsylvania.—As a result of the recent examinations held by the Pennsylvania State Board of Medical Examiners licenses to practise medicine were granted to 91 of 122 applicants.

Illinois.—On January 16, 17, and 18, 1907, the Illinois State Board of Health will hold an examination for license to practise medicine at the Great Northern Hotel, Chicago. The applicant must present a diploma from a medical college in good standing. Application must be made to the Secretary, Dr. James A. Egan, Springfield, Ill., and a card of admission to the examination secured. Students who are to graduate in 1907 will be required to present documentary evidence of preliminary education.

Virginia.—The Medical Examining Board of this State will reciprocate with boards of other States, but requires that every applicant claiming such recognition shall in person present with his petition a diploma from a reputable medical college, together with an attested certificate from a State Medical Examining Board having equal requirements with the Virginia Board, and willing and authorized to give similar recognition to those who hold Virginia certificates. Applicants complying with the above conditions and paying the usual fee, will be granted a certificate. The Medical Examining Board of Virginia declines to recognize the diploma of any college which does not conform to the requirements of the Association of Medical Colleges.

Medical Items.

Influence of Diet in the Treatment of Eczema.—A. Ravogli says that next to the kidneys the skin must be considered as an organ of elimination. Indeed it has more eliminating power for some products than the kidneys themselves. The occurrence of eruptions after the ingestion of certain foods is not accidental. The skin is active in eliminating substances which are detrimental to the general economy. The presence of toxic elements in the skin impairs its nutrition. Relapsing forms of acute eczema of the face which have been considered as nervous eczema often result from the ingestion of questionable foods. Individuals subject to eczema should subsist upon good, wholesome home cooking. The food should be fresh and not of a questionable nature. When products of fermentation develop in the stomach or in the intestines it must be admitted that there is a diseased condition of the functional activity of these organs. There is usually a catarrhal condition of the mucosa of the stomach or a nervous condition which brings about dyspepsia. The same conditions are present in the intestines. The diet in such cases must protect the parts as much as possible and eliminate nonirritating qualities. Food which leaves the smallest possible residue should be eaten. The writer believes that a coarse diet is better than a light diet. He advises the use of graham and rye bread together with honey, fruit juices, stewed plums, leguminous plants, boiled and baked potatoes; plenty of fresh milk, cream, and butter are also advised. Meats, beef, veal, fresh pork, boiled ham, chicken with plenty of vegetables are to be given without fear, as well as fresh white fish, trout, and so forth. Dark meats, venison, corned beef, mackerel, lobster, eel, and strong cheese are forbidden. Candies and sugar must not be taken. Certain obstinate cases of eczema of the face are due to the use of whiskey and chewing tobacco. Fresh country air and natural mineral spring waters are very helpful in the treatment of these cases. The influence of diet on the treatment of eczema in gouty people is almost incredible. The writer believes that obstinate infantile eczema instead of being due to the cutting of the teeth is rather due to the erroneous feeding of the child. In most of these little patients there is present a condition of enterocolitis.—*The Dietetic and Hygienic Gazette.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 28, 1906.

STUDY OF A CASE OF YELLOW FEVER.

BY A. E. THAYER, M.D.,

GALVESTON, TEXAS.

PROFESSOR OF PATHOLOGY, UNIVERSITY OF TEXAS, MEDICAL DEPARTMENT.

ON December 20, 1905, a patient was admitted into the John Sealy Hospital at Galveston, with the following history:

P. F., Irish, thirty years old, single, worker in silver. Family and previous history not important. On Friday, November 24, he left New York City for Jacksonville, Fla., arriving there on November 30, leaving again after eight days for Havana by way of Tampa and Key West. In Havana he spent twelve days, leaving on December 20 for Galveston, and arriving there at noon on Sunday, December 24. He had been very seasick after leaving Havana, and on the evening of December 24 felt chilly on going to bed, but slept well. On rising the next morning, and attempting to dress, he was dizzy and fell, striking the back of his head against an iron bed. He went back to bed and slept half the day, had a glass of milk for breakfast, but vomited it at 3 P.M. What he vomited on board the boat had been greenish; this was of a redder color. After 3 P.M. on Monday everything he took was vomited.

Admitted to the hospital on December 26, the patient was slightly jaundiced over the general surface and the sclerotics were muddy and more deeply jaundiced. He remembered having had slight frontal headache on the 23d. He vomited dark fluid when admitted, and, during the two days of his stay in hospital, twenty-one vomiting seizures were recorded on the bedside notes. The material ejected was always the same, in small or large amounts, thin and dark reddish-brown, semitransparent fluid, with finely divided, pulpy, granular material settling toward the bottom.

He was catheterized three times during the two days, the amounts obtained being two ounces, two drams, and three drams. Expressing this in cubic centimeters, and assuming that he should have passed 1,500 c.c. in twenty-four hours, the amount actually secreted during forty-eight hours was 65 c.c. instead of an assumed normal of 3,000 c.c. But, according to his own account, the patient passed no urine from his chill on the evening of December 24 up to the time of his death, four days later, except what was drawn by catheter during his stay in hospital. He, therefore, secreted but 65 c.c. in ninety-six hours, instead of 6,000 c.c.

His temperature had reached 103.4° F. at one o'clock on the 26th, from that point falling steadily to normal at 3 A. M. on the 28th, and remaining subnormal afterward. The pulse reached its highest on the 27th at 3 A. M., namely, 92, and thereafter remained about 74-80 till he died. Respiration varied between 20 and 14.

Soon after admission it was noticed that the movement of his tongue was impeded in some way, and upon examination there was found a small extravasation of blood beneath the right side of the tongue, involving the floor of the mouth also. This steadily extended until the entire right side of the tongue and adjacent tissues were involved, the dark bluish red hematoma raising the tongue and pushing it toward the left side. His speech became progressively laborious and indistinct. Up to a short time before his death his mind was perfectly clear, and he complained of nothing but pain in the right side of his chest, and faintness and dizziness. An hour before death he was slightly delirious.

The examinations made in the case were as follows: 1. Diazoreaction, negative. 2. Blood for malaria, negative. 3. Blood for cells, etc. Reds (first examination), 4,920,000; (second examination), 5,904,000. Whites (first examination), 8,800; (second examination), 4,950. Hemoglobin, 100 per cent. Malarial organisms, none. Small lymphocytes, 31.7 per cent. Large mononuclears, 1.5 per cent. Transitional, 1.3 per cent. Polynuclears, 65.5 per cent. Eosinophiles, none counted. Basophiles, none counted. Neutrophile myelocytes, 2 counted. 4. Widal reaction, negative. 5. Vomitus for Teichmann crystals positive (twice). 6. Urine: Specific gravity not determined, dark, amber, acid. Albumin, marked reaction by nitric acid. Many granular and some epithelial casts, much granular detritus, many red cells.

The patient died at 8 P.M. on Thursday, December 28, at the end of the fourth day of his disease, if the chilly sensations of the previous Sunday evening mark the commencement of the disease. The postmortem examination was held at 9 P.M. of the same day, one hour after death. The protocol is as follows:

General Inspection.—Body well nourished, warm, very slight degree of rigor mortis in muscles of lower jaw. Moderate degree of hypostatic congestion in the integuments of the back, with a few small punctate hemorrhages into the upper layers of the skin. General surface slightly yellow, sclerotics more deeply tinged with yellow. Superficial nodes of axillæ and inguinal regions a little enlarged. The hard palate is covered by a thin red film of coagulated blood. The right side of the tongue, for a distance of 6 cm. from the tip, is the seat of an extravasation which reaches to the middle line and partly involves the sublingual tissues.

Preliminary Internal Inspection.—The tissues of the thorax wall are edematous. The liver in the median line is 10-12 cm. below the xiphoid cartilage; the lower edge of the right lobe is at the right iliac crest in the midaxillary line. The gall-bladder is distended and projects 4 cm. beyond the free edge of the liver. The coils of small intestine are moderately distended with gas, the colon, except at the cecum, is partly collapsed. The omentum is well supplied with fat, and its veins are distended with semifluid blood. In the mesentery, at the ileocecal junction,

there are two small ecchymoses. The mesenteric nodes are congested and swollen. No adhesions or fluid in the abdomen. Diaphragm, fifth rib in midclavicular line on each side.

Thorax.—Triangularis sterni unusually well developed and of a uniform dark-red color, like all the other muscles of the thorax. The lungs meet along their anterior margins to a point opposite the fourth ribs. No adhesions or fluid in either pleural cavity. Pericardial fluid, 20 c.c., clear yellow serum. Heart: The blood of the inferior cava is fluid and its plasma is tinged reddish with dissolved hemoglobin. The endothelium of the heart and great vessels is yellower than normal. In the ascending portion of the aortic arch there is a slight imbibition of blood pigment; there are also a few small spots of atheroma in the first part of the arch; coronary arteries normal. The cavity of the right ventricle is a little dilated, the valves are all normal and competent, the muscular tissue is opaque, but there is no fatty change visible. Lungs: The posterior aspect of both upper and lower lobes is intensely congested and spotted with many small hemorrhages, as is also the pleura between the lobes. Pleura everywhere transparent and shiny. On section the entire lung on each side contains countless small hemorrhages, and much frothy blood-stained fluid flows from the surface of the incision. Bronchi intensely congested and contain a small amount of blood-stained froth. Vessels empty and apparently normal. Esophagus distended with bloody fluid, and presents a linear ecchymosis 5 cm. long in the upper third.

Abdominal Organs.—Spleen slightly larger than normal, capsule opaque and wrinkled, both fibrous tissue and lymphoid follicles more prominent than normal. Adrenals apparently normal. Kidneys: Normal in size, capsule adherent in places, surface dark and congested, stellate veins prominent, two small cysts in upper pole of left kidney, none in right. Markings not well preserved, cortex broad and opaque, lobules broad and yellow, especially in the lower zone of the cortex just above the pyramids, and here and there groups of straight tubes show broad and yellow on the congested background. Stomach: Contains 500 c.c. thin dark fluid, mucosa uniformly softened, with small punctate hemorrhages in it which are most numerous in the cardiac end. Common bile duct pervious. Intestines: The mucosa throughout both small and large intestines is edematous and covered with an excess of whitish mucus. The tips of the valvulæ conniventes are congested, and in places there are many punctate hemorrhages in the submucosa, especially toward the lower end of the ileum. The Peyer's patches are dark and prominent, and the solitary follicles are edematous. The contents of the small intestine are thick white mucus, which is tinged with bile in the duodenum and upper jejunum; in the colon there is a thin white fluid resembling milk (enema). Pancreas: Congested and its duct distended with secretion. Liver: Slightly larger than normal, especially the right lobe. Generally of a marked yellow color, which is most distinct in the peripheries of the acini. Urinary bladder entirely empty, ecchymoses under mucosa near the internal meatus; prostate edematous; seminal vesicles distended with semen. Abdominal and thoracic aorta filled with fluid blood. Trachea and inner aspect of larynx and posterior surface of epiglottis, intensely congested, with minute hemorrhages into the superficial tissues, and an excess of mucus on the surface. On section of the tongue the extravasation is found to extend beneath rather than into it, and is confined entirely to the right half.

Head.—Superior longitudinal sinus empty. Slight excess of serum in the meshes of the pia, both surfaces of the dura slightly yellow, internal carotids a little atheromatous. Brain generally congested, slightly edematous, and tinged with yellow.

Clinical diagnosis, yellow fever; pathological diagnosis, yellow fever.

Microscopic.—Portions of various tissues were embedded in paraffin and stained with the following: hematein, eosin; hematein, picrofuchsin; eosin, polychrome blue; eosin, Gram-Weigert; Nikiforoff's. The findings by these various staining methods are grouped together.

1. Brain. Portion of cortex in the Rolandic area of the left side. The tissue shows marked congestion and edema, the perivascular lymph sheaths are wide, there are no hemorrhages, the ganglion cells are cloudy and vacuolated.

2. Tongue. Muscle fibers swollen and stain unevenly with eosin. Striation in places fairly well preserved; on transverse section Cohnheim's areas are too distinct. The vessel walls and their investing endothelia are swollen. There is very free hemorrhage, the unaltered red cells separating bundle from bundle and filling the areolar spaces. In places there is marked cross fragmentation of the fibers. In other places neither striæ nor longitudinal markings can be made out, the sarcoplasm is broken into fine granules, imperfectly filling the sheath, and there are red cells within the perimysium.

3. Stomach. Tissue generally hyperemic with some hemorrhage. Almost no desquamation of epithelia, very few goblet cells, nuclei well defined. In the glandules the cytoplasm of the cells is much swollen, filling the lumina, the oxyntic cells suffer with the others, but no more than they. Pushing between the cells normally present are many large ameboid lymphocytes. Few small lymphocytes, no pus cells. In the lumina of some of the glandules the cytoplasm is breaking down by vacuolation and granular changes. The endothelia in vessels and lymph channels are swollen and tend to desquamate. All coats are edematous.

4. Small intestine. The tips of the villi are denuded of their epithelia in groups. Remaining epithelia are swollen and granular, and in many cases the cytoplasm is fused, cell with cell. There are very few beaker cells. Lymph channels are crowded with red cells, and their endothelia are large, swollen, and desquamating. All muscle fibers are edematous and stain badly, both in the muscle coats and the muscularis mucosæ, and their nuclei are coarsely granular. Scattered through the intestinal coats are a few eosinophile and a few polynuclear leucocytes, with a larger number of lymphocytes, chiefly large. Edema of all coats.

5. Pancreas. There are hemorrhages between the lobules. The ducts are distended with coagulated material, their epithelia are swollen, proliferating, and desquamating; the entire wall of the duct is edematous. The nuclei of the gland cells show marked karyolysis, the chromatin in many places being scanty and granular, and in others swept entirely out of the cell as fine dust. The same condition is noted in the epithelia of the main ducts. In the islands the cytoplasm of the cells is fragmented and fused, swollen and cloudy, and the nuclei contain but little chromatin. In the vessels, both arteries and veins, the wall is edematous, the lumen is full of blood, and the capillaries show frequent rhexis.

6. Liver. The hepatic epithelia show marked general fatty degeneration. There are but few free nuclei remaining, for the nuclei appear to suffer as early and as much as the cytoplasm. Here and there very large nuclei can be found, almost empty of chromatin, with a very distinct eccentric nucleolus,

and the latter is acidophile. Other nuclei show karyorhexis, but this is limited to a few cells. Between the liver cells are occasional ameboid lymphocytes. The capillaries are very hyperemic, especially those of the portal system. The smaller bile ducts are everywhere occluded by swollen and desquamated epithelia, in places forming a tightly-packed granular mass, so that the structure is not recognizable as a duct. Many of the liver cells contain granules of precipitated bile pigment. Much of this lies within the partly empty cell membrane, amid granules of broken-down cytoplasm, but there is also a high proportion of such pigment, in the aggregate a great deal, which lies free in the capillaries leading to the central vein; the bile pigment thus has a direct access to the systemic circulation. The large ducts are somewhat similarly affected, but there are many with a lumen. Kupfer's stellate cells are swollen and dividing. The large increase in pigment in the liver points to active erythrolysis in some part of the portal territory, and to the alimentary tract as the place of entry for the disease. The ability of the liver to destroy or hold back the toxins would soon be exceeded, and they and the bile would enter the general circulation together.

7. Abdominal node (mesenteric). Apparently a rapid proliferation of small lymphocytes, the germinal areas being remarkably distinct and tightly packed. The small blood-vessels are partly occluded by swelling of the endothelia. In the main lymph channels the endothelia are swollen, and tend to desquamate, but are not fused. But very few polynuclears are noted. Whole tissue is edematous. In the adjacent fat tissue there is edema with capillary hemorrhages, and the nuclei of the fat cells are vacuolated.

8. Heart. The muscle fibers are swollen and irregular in outline, in places vacuolated, the nuclei very much swollen, and with indented edges. Much fragmentation in places. The usual pigment at the poles of the nuclei is absent, and triangular clear spaces are found instead, in which an occasional granule of hemofuscin remains. The tissue is generally hyperemic and edematous, and there are a few minute hemorrhages. The walls of the vessels are swollen. No cellular exudate observed.

9. Lung. The hyperemia in the arterioles and capillaries is extreme, many of the smaller vessels being full to bursting, with frequent hemorrhage both by rhexis and diapedesis. Many of the septa between alveoli are packed with red cells and many alveoli are full. In form the red cells are normal, except that the central pale area is a little larger than normal, the rim is slightly swollen, and the disk is more cupped, but there is no crenation, anomaly of form or size, or destructive process observed in the extravasated red cells. The epithelia in the alveoli are swollen and opaque, but their nuclei stain well. Many of the respiratory bronchioles contain red cells. There is remarkably little pigment in the fibrous tissue of the lung.

10. Adrenal. The cells of the glomerular zone and of the outer fascicular zone show swollen nuclei, the cytoplasm washed out, and the cell empty except for a few delicate strands. The cells of the lower fascicular and reticular zones are pigmented by a fine reddish-yellow amorphous intracellular dust. In many of these cells the nucleus is merely an outline, free from chromatin. The capillaries all through the organ are hyperemic, with a few minute hemorrhages.

11. Kidney. All the epithelia throughout the organ are swollen, in many places completely closing the tubules; this is especially distinct in the convoluted tubules. Many of the tubules are filled with homogeneous acidophile casts. In some of Henle's loops the entire epithelial investment is partly separated from the wall, but generally there is but little desquamation. The glomeruli are swollen, very hyperemic, and compressed somewhat by amorphous pale material between the layers of their capsules. This is in part derived from the cytoplasm of the epithelia, which are scanty and degenerated, some cells appearing as round opaque globules lying free in the amorphous material; part of it is probably proteid derived from the blood, and unable to escape through the occluded tubules. In view of the degree of active hyperemia present, there are remarkably few hemorrhages in the organ.

12. Spleen. The lymphoid follicles are large, their vessels are partly closed by swelling of their endothelia, and their walls are wide, and in places structureless, from edema. In the larger arteries the nuclei of the muscle cells are much swollen and distorted. The vascular spaces of the pulp are crowded with red cells, which appear of normal outline. Among the white cells present are many eosinophiles.

13. Prostate. The organ is hyperemic and edematous. Epithelia are swollen, granular, and opaque, their nuclei vesicular, and chromatin scanty. Gland and duct lumina are more or less filled with detritus and some desquamated epithelia.

By Nikiforoff's method some of the prostatic epithelia show a tendency to take the indulin strongly. In the adrenal some of the cells pick out the aurantia, and the nuclei are acidophile; other cells refuse both aurantia and eosin. In the pancreas an occasional cell is acidophile, the islands do not stain, the capillaries of the islands show especially wide and empty; in the ducts there are some acidophile and degenerated epithelia, and nuclear lysis is very distinct. In the intestine nothing stains except the red cells, so that the villi look like sacs stuffed with red cells.

With Gram-Weigert stain no fibrin is found in any of the organs, even where the fluid exudate is most copious and the effects of the edema most clear.

Summing up the microscopic features of the case, we recognize:

First, an intense and general edema, involving all the tissues examined, and in general it has acted destructively on both cells and nuclei, tending to dissolve out chromatin from all nuclei. This is more important than appears at first sight, since the patient ingested no fluids which could be retained.

Second, there is a severe effect upon the walls of vessels, especially of small arteries and capillaries. This includes swelling of endothelia, desquamation of endothelia, such imbibition of fluid by the media and other coats that they may become structureless and none of the elements present will stain, and, lastly, increased permeability (of capillaries especially) with rhexis.

Third, there is a pronounced and destructive effect upon epithelia, which is twofold in nature, partly the result of imbibition of fluid, and partly the result of a diffusible toxin. There is nothing catarrhal about it, no tendency to produce profuse mucinous discharges, no great desquamation of dead cells in masses, no large collections of leucocytes, either polynuclear or other forms. Furthermore, there is no fibrin in the exudate in any of the organs examined. The destructive effect upon epithelia is widespread, but most distinct where the cells are most highly specialized, as in liver, kidney, and adrenal, but of the same character everywhere.

Fourth, there is no cellular exudate anywhere.

Fifth, there is no hemolysis. The red cells, both in the vessels and extravasated into the tissue, are apparently normal, except for some swelling, and this is probably a post-mortem change, for even in the hour between death and the autopsy there was time for slight staining of the endothelium of the ascending arch by dissolved hemoglobin, and swelling of the red cells is the first step of the process which leads to this effect.

FIG. 1.—Small round and ameboid forms from the mucous surface of the ileum; one presents two vacuoles; one lies in an empty red cell with a finely granular border; the accompanying bacilli also stain.

Of course, all this applies to this single case, dying on the fourth day of the disease, and is not supposed to apply to any other case.

Microorganisms.—By the Gram-Weigert method, preceded by eosin, a number of large boat-shaped bacilli were found in the pancreas and among the epithelia of the small intestine. This was an accidental find and was not followed up, as it was felt that ordinary bacterial stains of all kinds had been tried so thoroughly that it was unnecessary to repeat them.

The following staining method was adopted after numerous unproductive efforts:

Material is hardened either in 5 per cent. formalin solution, made with normal salt solution, for 24 hours, or in saturated bichloride solution in normal salt for the same time; it is then transferred to 95 per cent. alcohol. Imbedding in paraffin is as follows:

Out of 95 per cent., to absolute, alcohol 4-6 hours; anilin oil, 3 hours to overnight, excess removed by filter paper; xylol, 3-4 hours; soft paraffin, 3-4 hours; hard paraffin, 3-4 hours. The last three steps are sometimes best carried out at 37° C. Sections were cut 5-7μ, flattened in warm water, and fastened to the slide in the drying oven at 38° C. overnight. The slide is then freed from paraffin by flooding with xylol, dipped in 95 per cent. alcohol, and before the section is quite dry a few drops of the stain are added. This consists of

Solution of ammoniated oxide of copper	10 c.c.
Glycerin	10 c.c.
Saturated alcoholic gentian	30 c.c.

The stain acts for 15-20 minutes, and is decolorized by flooding with ½ per cent. HCl in alcohol, ceasing before all the color is extracted. The section should have a delicate bluish tinge. Usually one minute is enough. To the acid alcohol a trace of eosin or basic fuchsin may be added as a contrast stain. The section is dried with blotting paper cleared with xylol and mounted in balsam.

Results.—Wherever the capillaries contain red cells, some of these present within their bodies deeply stained blue or purple bodies. The balance of the cell is not stained by the gentian, or only faintly so; with a contrast stain, of course, it will have no bluish tinge. Some of the blue staining bodies are free. Such extracellular forms were observed on the surface of the ileum, among desquamated epithelia, and extravasated red cells, and in the glandular spaces of the prostate they were very numerous, but they occur in all the tissues examined, lying either in capillaries, lymphatics, or tissue spaces. Others were found in endothelia, or, rarely, in epithelia, as in the kidney.

In size these bodies vary from a round point in the body of a red cell, of less than one-fifth the diameter of the cell, that is, about 1-2μ, up to a body which occupies all the cell except a narrow margin (Fig. 2, Nos. 2 and 4). Between these extremes of size are various ameboid and horseshoe forms. Where red cells lie in small capillaries as elongated oval or triangular objects, the stained body frequently occupies one end. In some red cells the ameba shows distinct pseudopods (Fig 2, No. 2), and in the intestinal wall, the prostate, kidney, and elsewhere, such ameboid forms have been found free. In an endothelial cell, desquamated from a lymphatic in the submucosa of the ileum, a small elliptical body was found, lying in a space in the cell protoplasm, which it did not entirely fill, the unstained cell nucleus lying at the side. A similar observation was made on a large lymphocyte, which presented no nucleus (Fig. 2, No. 5).

Where hemorrhages occur, as in the alveoli of the lungs and upon the mucosa of the ileum, infected red cells are often found, with the proportions between cell and ameba varying according to the development of the latter, and among these are unstained, uninfected red cells. Occasionally red cells have been found with more than one dark-blue body inclosed, recalling multiple infection with plasmodium malariæ and pyrosoma bovis.

FIG. 2.—Intracellular forms. 1. Small round body at one end of a compressed red cell in a narrow capillary. 2. Red cell with large vacuoled ameboid body. 3. Small round body in the cytoplasm of an endothelial cell, its nucleus laterally displaced. Taken from a lymphatic of the submucosa of the ileum. 4. Horseshoe form in a red cell. 5. Oval body lying in the cytoplasm of a large lymphocyte, its nucleus not seen

Occasionally a capillary is so filled with red cells, which carry these blue bodies, that with a low power the vessel stands out as a solid cord among the unstained elements.

The distribution of the amebæ varies in different tissues and different parts of the same organ. In

the kidney they are found in the small vessels proximal to the glomeruli, distinctly but scantily in the glomerular loops, and still fewer on the distal side. In the convoluted tubules only a few epithelia were seen, which contained the small blue bodies, and here and there one lies free in the lumen of the tube. A few casts in the deeper portion of the cortex were slightly tinged with blue, as if material from amebæ were contained in them. In the liver numerous examples may be seen in one field, and but few in another. Here and there the swollen, unstained nuclei of the hepatic epithelia appear to contain small blue bodies, and these probably are not chromatin particles, for the stain does not persist in nuclei. In the lung the amebæ seem to be less numerous than elsewhere; in the spleen they showed particularly well after the bichloride method of hardening; in the mucosa and submucosa of the ileum and stomach very clear pictures were obtained, both of free and of intracellular forms.

Interpretation.—This method of staining does not stain either the cytoplasm, the nucleus, or the nucleolus of the cells in the body, with the exception that in the bichloride series some of the red cells were faintly tinged in a diffuse manner if decolorization had been incomplete. It does not stain either the red or the white cells in blood films. It does not stain the ameba coli, in the few cases thus far tried. The method does stain the pus cocci, but not very well; the tubercle bacillus stains well, even in tissues where it is difficult to find it by carbol-fuchsin, and the malarial organism in blood smears is very distinctly stained. Hence the blue bodies found can not be due to a reaction with normal hemoglobin, or they would occur in blood smears; nor are they due to reaction with hemoglobin altered in the course of yellow fever, for among the red cells which bear them are others which do not stain; in red cells which are almost filled by these bodies there is often an unstained margin about the parasite; in some red cells the ameboid margin, with pseudopods, has been distinctly seen, while the balance of the cell is unstained: the same is true where the parasite occupies one end of a compressed red cell, and other forms occur where the ameba is of a horseshoe shape, with rounded ends, within the body of the red cell. When the ameba is free it often has small pseudopods (Fig. 1). There is a regular gradation in shape and size between the small round dot in a red cell, of one-fifth the cell's diameter or less, up to a body which entirely occupies the cell's capacity. The small and middle-sized forms are often provided with one or more vacuoles, seldom more than two. With the method described the blue ameboid objects are the only elements stained in sections of various organs. Taking all these facts together, the blue ameboid bodies can not be regarded as artefacts nor as elements of the tissues.

The internal structure of the ameba is difficult to make out, and this is one point in which the method needs improvement. The staining is usually dense and uniform, except for the presence of vacuoles, but no nucleus is visible, and no pigment. In some of the forms observed after bichloride hardening there were a few of the amebæ which presented a reddish tinge on one side; this may perhaps prove to be nuclear.

From this single case it can not be claimed, far less proved, that the ameboid bodies observed are causal in the disease known as yellow fever, though provisionally the name *Amœba febris flavæ* may be suggested. Before such a claim can be made the following conditions should be fulfilled:

1. The same bodies must be found in the organs of other cases of yellow fever, and early autopsy is probably important.

2. They should be found in the blood of yellow fever patients, in all probability within the first three days of the disease, for transmission by the stegomyia occurs only during that period.

3. They must be found, under some guise, in the tissues of mosquitos known to be infected.

4. More than one observer, in different parts of the world, should find and identify them.

5. They should be cultivated, but here, as in the case of the malarial parasite, the condition is not urgent for the mere establishment of a causal relation.

All these conditions imply access to fresh cases of the disease and to infected mosquitos, which is not the good fortune of the writer.

In conclusion, it is my pleasant duty to express my thanks to Prof. Marvin L. Graves, in whose service the case occurred, for permission to report it; and also to Prof. E. C. Schneider, of the Colorado Springs College, who placed at my disposal the resources of his laboratory, and thus enabled me to complete the case during my vacation.

PRACTICAL POINTS IN THE OPERATION OF COLOSTOMY.

By CHARLES B. KELSEY, M.D.,

NEW YORK.

To one as thoroughly convinced as the writer of the great benefits of this operation in many cases, it seems strange that the natural objections to it held by the profession at large, and especially that part of it devoting itself to medicine rather than surgery, should not, ere this, have been more completely overcome. That the operation has been abused admits of no more question than that the family physician often prevents his patient from receiving the benefits which would certainly follow its performance.

In trying to point out concisely the real indications for this most valuable addition to the surgeon's weapons for combating disease, a certain allowance must be made for personal feeling on the part of surgeons and for honest differences of opinion. Some will advise it much more frequently than others, according to their own experience of its advantages. There is hardly room, however, for any such radical difference of opinion, as was shown by an enthusiastic young operator who had taken a short course in diseases of the rectum under me some years ago, and then started practice in the West, who wrote to me after a few months that he had already done the operation twenty times, but his county society was making him trouble, and he wished to know how many times I had done it during the same period. My answer was in one word, "once," and I was then running a large clinic.

In most cases there should be no uncertainty. Take, for instance, cancer of the rectum which is inoperable. No palliative measure has ever been devised approaching colostomy in its benefits, where it is done, as it always should be, early. The average duration of life in this disease is supposed to be two years, though such an estimate may be open to question from the impossibility of fixing, with any accuracy, the time of its onset. But, accepting this from St. Mark's Hospital as being correct, I have had many cases where the operation was done after the disease had existed fully as long as this, in which the

patient has lived in comparative comfort from two to five years after.

In fact, I will venture the statement that in cancer of the rectum the average duration of life is much longer after colostomy than after extirpation, though of course there is never a cure. So plainly has this been demonstrated in my own practice for years back that some of my associates have made up their minds that if they ever found themselves afflicted with this dread disease they would take a simple colostomy, and let it go at that.

Of course, there have been the usual number of unsatisfactory cases and fatalities—cases done "after there were symptoms of obstruction," as so often advised by the medical attendant, and cases in which there was already undiscovered metastasis, and in which the operation on this account has not been worth the while. But, setting these aside, I cannot state too forcibly the simple fact that in my cancer cases, in which extirpation was impossible, the relief given by this treatment has earned me the heartfelt gratitude of many patients who have found themselves slipping quietly and painlessly down to the grave from gradual exhaustion. And, with this experience behind me, my lack of sympathy with other palliative measures may easily be understood.

Colostomy in cancer relieves the constant bearing-down pain; prevents abrasion of the surface and consequent hemorrhage; prevents the formation of abscesses and fistulæ in the vicinity of the disease, and slows the growth by avoiding the irritation due to natural defecation. Its danger, when done early, is almost nil, but this danger increases directly in proportion as the disease advances, until where chronic obstruction has actually been established, it reaches 33 per cent. Why, then, delay till obstruction sets in? Simply from an exaggerated idea of the discomforts attendant upon this means of relief—an idea which any extended experience will certainly overcome.

Congenital malformations of the rectum and anus constitute another of the strongest indications. Not all of them, by any means, but some of them.

Think of a man born with an imperforate anus, and living for forty odd years with a bath sponge tied against the fistula, resulting from the puncture by a trocar! During all that time the entire colon had been a reservoir for solid feces, and when I did a colostomy it was hypertrophied from cecum to anus to three-eighths of an inch in thickness. He died from acute dilatation of the stomach, due to unloading the colon, which filled the entire abdomen.

In all this class of cases colostomy is the last resort after every effort has been made to establish an outlet at the natural site, but it sometimes is manifestly the only way of prolonging life.

Cases of extensive ulceration are more frequently an indication for an artificial anus than are the benign fibrous strictures. And destructive ulcerative processes which can be made to cicatrize by no other treatment will often heal quickly after the flow of feces has been diverted. In the benign strictures I do not use this method of relief as often now as formerly, having learned by experience how long and in what comparative comfort patients may bear this condition. The chronic hypertrophic proctitis, which is the cause of the lessened caliber, seems in many cases to be self-limiting. There is little or no cicatricial contraction to be overcome which might in time cause complete obstruction; but a thickening and infiltration of the wall of the gut and surrounding tissue, which once having taken place remains comparatively stationary and does not advance. The formation of abscesses and extensive fistulæ in the neighborhood of the stricture is more to be feared, and is a stronger indication for colostomy than the mere narrowing of the canal, which can generally be quite satisfactorily managed by other methods.

Rectovesical fistula in either sex, unless very small, usually calls for prompt relief by this means, and so do some of the more extensive fistulæ where there is no communication between neighboring organs. For fistula is not always curable by cutting, nor is attack upon the extensive tracts always justifiable, even when the disease is destroying the vital powers. Many of them have to be borne, and those which cannot be are often best cured by an artificial anus—in fact, can only be cured in this way.

In acute intestinal obstruction from any cause (volvulus, intussusception, enteroliths, bands, apertures) the conditions found in each case upon opening the abdomen will decide for or against establishing a temporary or permanent artificial anus.

There is, I think, a growing feeling that in all cases in which any sort of artificial anus is necessary the colon in some part is the most convenient place for it; and, as a more or less artificial anus (generally more) is a necessary result of nearly all cases of extirpation of the rectum, if this idea finally prevails the operation of excision will be one of the most frequent of all the indications for colostomy. With me this idea has always had great weight, simply because, as a rule, the patients upon whom I have done colostomy for any cause, have been cleaner, more comfortable, and have had better control of the passages than those upon whom, after extirpation, I have made the gut to end as near the natural anus as the operation allowed. This is a matter upon which one can speak only in a general way, and there are exceptions, but anything like sphincteric power after any variety of excision is very rare. These patients usually have a good deal of difficulty in keeping themselves clean, whereas one with a *properly formed* opening in the groin will have no difficulty whatever. Even if there be no real sphincteric power, the bowels may be educated to move once a day, and very often no receptacle need be worn, the opening being covered merely with a pad of lint held in place by a light abdominal bandage.

Of the surgical advantages of always doing a preliminary colostomy before extirpation I will not speak. There is much to be said in its favor, but we are now considering the question from the patient's standpoint of personal cleanliness and comfort, and I am often surprised to find that those with whom I have taken the greatest care to make a temporary opening which could be easily closed, decline the second operation as not being worth while. Nor is this only with men, but it applies equally to women, and not necessarily in the lower walks of life.

A question now *sub judice* is whether mucous colitis is an indication for colostomy or appendostomy, and in what class of cases. It has not won its way as yet with conservative advisors, and my own feeling is that its advantages will

have to be proven beyond a peradventure before it ever will. Too many family physicians are convinced of the nervous causation of the symptoms which make the condition to have them recommend any kind of local treatment very enthusiastically, and especially this operation. The question must be left to time, and will be settled rather in the hospital ward than in private practice.

Technique.—The operator should have a prety clear idea beforehand whether the opening is to be permanent or only temporary. If the former, certain steps may be taken to insure absolute efficiency and the greatest amount of control with the certainty that nothing can pass below the opening—the chief essentials. If the opening is to be only temporary, more regard must be paid to the future closure, and efficiency must be somewhat sacrificed in order that the gut be as little injured as possible in the primary operation. In this, as in other things, the personal equation will modify the author's choice of method. With myself, most colostomies are intended to be permanent, and even in those which I have intended to be temporary I have not always been able to get the patient's consent to a second operation, for the reason given above. A few times I have been called upon also to close what I had supposed would be a permanent condition on account of the cure of the disease, and here the operation has been much more extensive than the colostomy; so that the technique is not in its final stages the same for the temporary and permanent operations, and the distinction is practically important, and can usually be made beforehand without making a large incision into the abdomen for exploration by the whole hand, and utilizing this for the artificial anus—a method with manifest objections. The debatable cases are the extirpations. If the operator believes a sacral or ischiorectal artificial anus has sufficient advantages over an inguinal to make it worth while to close the inguinal, which has been formed merely as a source of additional safety during the operation of excision, he will make many more temporary than permanent openings. Otherwise the temporary openings will be confined to the cases of benign ulceration, extensive fistulæ, and some of the cases of acute obstruction. In my own practice I do not find "provisional colostomy" at all necessary to the success of an extirpation, and if I did I should not think of closing it after making it; so it results that most of my own cases are permanent.

There is no necessity for going over all the details of the operation found in the text-books, but a few points may be dwelt upon with advantage. Nearly all of the many modifications which have been made since the operation became thoroughly established have been in the line of elaboration rather than simplicity. The Mayde-Reclus method of substituting a glass rod for a suspensory suture under the gut, and the omission of any suturing to the abdominal wall is about the only exception. So that now the operator who has had little experience and no fixed ideas on the subject is fairly flooded with methods from which to choose. There are spurs of all sorts, stitches of all sorts, openings in the inguinal region, over Poupart's ligament, and down the thigh. The bowel is incised lengthwise, and transversely, or both ways. A recent text-book describes thirteen different recognized procedures, with the names of their sponsors; so that the state of mind of the operator may be thoroughly appreciated who wanted my advice the other day, not as to the advisability of the operation, and not as to its permanency, but as to the value of these elaborations, and how best to operate.

Regarding the Mayde-Reclus method, which is a modification of my own, its simplicity is not devoid of danger peculiar to itself, and it should not be trusted except in cases of very small incision tightly plugged by the loop of gut drawn through it. More than once a hernia of small intestine has escaped between the incision and the loop, and in one case of my own this accident ended fatally. There is no occasion for any such risk. The glass rod simplifies the operation, and, if left *in situ* two or three weeks, makes a good spur; but two or three sutures in addition will make all safe, and should not be omitted.

My own method has changed but little, in spite of the changes by others, and the same is the case at St. Mark's. The incision was for a time unnecessarily large. It is now half the length and "gridironed," as in appendicitis. In other words, muscles are separated as far as possible, and fibers cut as little as possible, and an opening one inch long will usually allow the insertion of the index finger, the hooking up of the sigmoid, and pulling it out of the abdomen. If, as I hold, as useful and cleanly an opening can be made in this way as by any more elaborate effort at sphincteric power by carrying the loop to a distance from this opening through other muscles or under the skin, and closing this opening for another more or less removed from it, these modifications, which constitute most of the supposed improvements, will not hold their own. I have never adopted them.

It is unfortunate to so far improve upon an operation as to spoil it; but not long ago I had a very serious time in resecting one of these long intermuscular and subcutaneous outlets, which was a mere fistulous tract, and giving the patient a real anus to overcome chronic obstruction.

In the temporary operation, pass the sutures through the edges of the abdominal incision, the parietal peritoneum, and the wall of the gut. In the permanent operation *do not* include the parietal peritoneum in the suture.

The reason is obvious. If the parietal peritoneum be left out a firmer union between gut and abdominal wall is secured than when the two peritoneal layers are united. In the latter case, the gut, though not as well adapted for permanency, is more movable, is more completely shut off from the general peritoneal cavity, and can often be closed by an operation which shall not extend into the cavity.

In temporary colostomy make a free longitudinal incision in the gut, but cut away none of the intestinal wall. In permanent colostomy trim the gut freely down to the edges of the abdominal incision. In both keep the opening into the gut between the spur and the upper angle of the wound, and do not cut into the bowel below the level of the spur. In this way feces are forced to the surface by the spur and by the partially-contracted lower segment of the gut beyond the level of the spur, and the longitudinal section, with no sacrifice of tissue, is much more easily closed by subsequent operation.

Were it not for one thing, the lower segment could, with advantage, be invaginated and dropped in every permanent operation; but it is often of advantage to wash through it from above downwards, and when the upper end is thus

closed I have known a collection of mucus and discharge to accumulate in the cul-de-sac to a tumor the size of the fist, and cause great pain and very acute symptoms before being relieved.

In cases of severe or long-continued chronic obstruction, operate on the right side instead of the left, and make the opening temporary, with the idea subsequently of enlarging it and allowing it to remain, or preferably closing it and substituting an opening on the left, if conditions admit.

The reason for this is that in such cases the greatest accumulation is often in the cecum; that the sigmoid is likely to be so distended with solid feces as to make a proper colostomy opening impossible until it has emptied itself; and that an opening in the sigmoid, even though large and free, may fail entirely to give relief to the distended large bowel before fatal results are caused.

This has happened in my own practice from failures to exactly appreciate the conditions existing. The patient, with cancer of the rectum, was an exceedingly large man, though emaciated, still weighing at least two hundred and fifty pounds, and the abdomen, although very large, was not at all distended, nor were there signs of obstruction. In fact, he was having solid passages by the aid of laxatives every other day, but the feces consisted only of two or three large scybalæ. An opening was made as high in the sigmoid as possible, and the gut was found only moderately full of hard fecal matter. Thinking we might have trouble, the opening was made much larger than usual and the stitches placed very strongly and with care, and an excellent spur was formed, but within forty-eight hours the whole sigmoid and rectum, both above and below the opening, were flooded and packed with solid masses, and the artificial anus gave no relief whatever. Several times these were removed with forceps and the finger, but without any relief, and in the end the pressure of this avalanche was too great, the adhesions between the bowel and the abdominal wall gave way, and fatal extravasation into the peritoneum occurred. A second temporary opening into the cecum should have been made, and might have saved the patient.

In making an opening into the sigmoid make it as high up as possible to avoid prolapse, and in the cecum make it as far from the valve as possible, to prevent the end of the small gut being pressed directly into the opening in defecation, thus allowing the direct evacuation of fluid feces. This is always the objection to cecostomy, and, although in time the evacuations may become formed, it is a serious one. Another is that the whole large bowel is cut off from the economy, and, though patients seem to bear this remarkably well, it is more than probable that it has in nature some function besides a mere reservoir, and that patients are better with than without it.

Any of the operations for an artificial anus may as well be completed at the time as to wait two or three days before opening the gut. All that is necessary is to guard against feces soiling the peritoneum, and a few sutures carefully placed will eliminate any danger of this kind. The opening of the bowel is not painful, however, even when postponed for adhesions to form; but, until it is opened, there is generally complete obstruction at the site of the spur both for gas and solid matter, and the condition of the patient must be carefully watched. Often in forty-eight hours all the symptoms of acute obstruction may be distinctly marked, and the gut must be opened without further delay.

I have known a man to die of obstruction in a hospital ward after a colostomy while the operator was waiting for the adhesions to become firm enough for the gut to be incised.

Sigmoid colostomy may be impossible for three reasons. The gut at this point may have no mesentery; it may be so implicated in cancerous disease as to be either unrecognizable or absolutely fixed and immovable, or it may be overdistended with feces so that only a lateral incision without a spur is possible. In all these cases the abdominal incision should be closed. In the last a temporary opening should be made in the cecum with the expectation of making a permanent colostomy after the bowel has been evacuated. In the other two conditions a permanent anus should be made in the transverse colon, as near the splenic flexure as possible. Here we secure solid passages and cut off no more large bowel from the economy than necessary.

A temporary anus made as here described may generally, and a permanent one may frequently, be closed by a plastic operation without opening the peritoneal cavity. As the first step toward this the spur should either be destroyed or pressed back. Destruction may be by excision or by sloughing from the grasp of any form of pressure forceps. As there is always some danger from the enterotome, Banks' method by elastic pressure upon the spur should first be attempted. This consists in introducing as large a piece of thick rubber tubing into the proximal and distal ends of the gut as these will admit, and fastening it in this position for several days. This is accomplished by passing a piece of aluminum wire through the side of the tube (not the caliber), bending the ends over the edges of the abdominal incision, and holding them with adhesive plaster. The rubber will cause pain, but can generally be borne, and after three or four days the spur will be found considerably reduced and the contracted distal orifice considerably dilated.

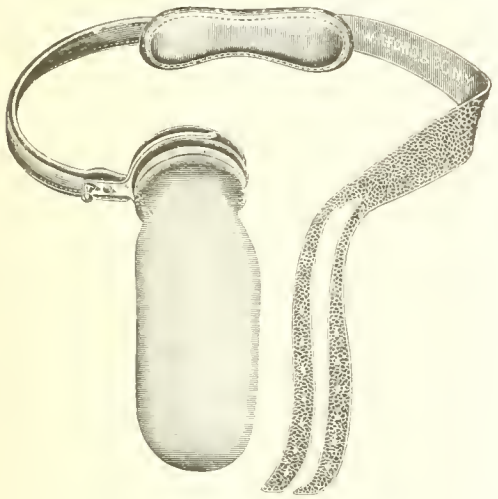
When this has been accomplished, the edges of the gut, with the cicatricial tissues, are dissected free from the parietes *down to* the subperitoneal fat on all sides, and the parietal peritoneum, with its fat, is stripped from the abdominal wall to a sufficient extent in every direction to allow free mobility of the gut, and partial or complete withdrawal of the part to be sutured from the wound.

This dissection should not be begun in the cicatricial tissue at the sides, where the parts are matted together, and there is more or less ectropion, because the peritoneal cavity may be opened before the operator knows just where he is; but a clean incision in normal tissue should be made from the upper angle of the anus upward for at least an inch, and from the lower angle downward for another inch, and when subperitoneal fat and peritoneum have been recognized at these two points, blunt dissection with the finger and a few strokes of the knife will loosen the sides of the opening, and permit the drawing out of the portion of bowel to be sutured. The opening in the bowel is then closed carefully with Lembert sutures passed through the cicatricial edges. No sacrifice of tissue should be made to secure clean approximation of peritoneal surfaces, for this is not necessary. The suturing must be adapted to the nature of the opening which has been made,

and may be transverse or vertical. Where much bowel has been sacrificed in the original operation, it must be transverse; hence the advantage of a longitudinal incision without sacrifice of the wall.

Where too much bowel has been resected to allow of this plastic procedure, the problem is simply one of end-to-end intestinal anastomosis. I have a favorite Murphy button which has done its work successfully four times in these cases, and the recent experiments of Cannon and Murphy would indicate that end-to-end anastomosis is always preferable to lateral, in that the circular fibers are not cut longitudinally, and peristalsis is not, therefore, rendered impossible.

As to plugs to close the artificial anus, and receptacles worn to collect escaping feces, the former I never use, and the latter are by no means always necessary. Often a simple pad of cotton and a body bandage answer better than any more elaborate contrivance, and the bowels can usually be trained to act but once a day, and this with solid movements. Should any contrivance be desired, however, an excellent and very simple truss can be made to meet the indications for support.



The one shown in the cut was made for me by Ford & Co., some years ago, and seems to have given satisfaction to both surgeons and patients. It is a simple truss with a fork at the end. Between the two prongs of this fork slips a flat, hard rubber ring about an inch thick and two inches in diameter, and onto this ring the soft rubber pocket is held by its own elasticity. The contrivance is light, firm, and cleanly. Most of those pictured in the textbooks are unnecessarily cumbersome.

44 East Twenty-ninth Street.

A GENERAL CONSIDERATION OF DEMENTIA PRÆCOX.

By EUGENE F. McCAMPBELL,

COLUMBUS, OHIO.

FORMERLY ASSISTANT IN PATHOLOGY, COLUMBUS STATE HOSPITAL FOR INSANE; LATE PATHOLOGIST TO MINNEQUA HOSPITAL, PUEBLO, COLORADO; INSTRUCTOR IN BACTERIOLOGY, OHIO STATE UNIVERSITY, COLUMBUS, OHIO.

Of the many forms of insanity which are found among those who populate the hospitals for the insane throughout the country, without a doubt one of the most prominent, and one which attracts our attention as much as any other, is dementia præcox. This psychosis is also known by a variety of other names, such as primary dementia, adolescent insanity, juvenile insanity, stupiditas, etc., and, as these names signify, the disease is one which has its outset in early life and it usually ends, after running a chronic progressive course, in a state of mental apathy and deterioration. The state of profound dementia is usually preceded by a preliminary state of depression varying in length, but nearly always terminating in complete lethargy and indifference.

About fifteen to twenty-five per cent. of all admissions to hospitals, according to Kraepelin, are patients suffering from this form of mental disease. It has only been in the last few years that the disease, as such, has been recognized. Formerly these cases were classed among the imbeciles and idiots, or, to use the general term, "dements."

It is only necessary to investigate the histories of many of the so-called imbeciles and idiots who have been residents of the hospitals for years to find that in early youth many of them were children of ordinary mental capacity, and that some had even been exceptionally intelligent. We find oftentimes in these cases that some time about the age of pubescence, and on up to their thirtieth year, these men and women suffered some attack of mental disorder which has left them, after many years, in this state of progressed dementia.

The term dementia præcox is one of some fifteen years' standing, being first used by Pick[1] in 1891. At this time he applied the term to a class of cases which we now call hebephrenia or hebephrenia gravis. Its usage has since been broadened, and it is now made to include a large variety of cases.

In our opinion, by far the best classification that can be used in separating the various cases which are placed under the head dementia præcox, is that of the German psychiatrist, Kraepelin. The disease may be said to include, according to Kraepelin, (1) Hebephrenia, a term first applied by Kahlbaum and Heckter to a class of cases which sometimes show maniacal symptoms, but rapidly terminate in a state similar to melancholia; (2) Katatonia, first used by Kahlbaum in 1874 to designate a class of cases having a stuporous condition with negativism, automatism, stereotypy, echolalia, echopraxia, etc.; (3) Paranoid dementia, being applied to certain forms of paranoia which terminate with decided mental impairment and degeneration.

Psychical Symptomatology. — Considered as a whole, dementia præcox is not difficult to diagnosticate, especially in its early stages, although a train of symptoms which is most varied is often presented. To diagnose the various forms of the psychosis is perhaps more difficult, and it may not be amiss to consider the symptomatology of these various types of dementia præcox.

Hebephrenic Form.—The development of this form of the psychosis is usually very gradual. The first manifestations of the disease are frequently the display of a violent temper without cause, irritability and restlessness in some cases, while in others the first change noted is the difficulty in the concentration of thought, and with this comes a loss of interest in everything, and lack of energy. In the restless and active type of hebephrenia the patients are often found assuming peculiar attitudes. They walk about the wards picking up pieces of paper, rags, etc. They grin foolishly, and frequently burst out into loud laughter without cause. Others of the more depressed type sit for hours at a time on a seat, the head cast down, and facial expression apathetic. Some patients seem immobile, and will not change their position except when forced to do so. Frequently they refuse to eat, and remain in a state of absolute mutism. It is not a defect in speech that prevents these patients from talking; it is sim-

ly because they have nothing to say. It is sometimes difficult to differentiate between hebephrenia and katatonia in some cases of this kind. Not infrequently, seized with sudden impulses, some of these patients will suddenly start up from the position they have held for some time, grasp some object, and throw it. Often these impulses take the form of suicidal and homicidal tendencies, and the patients make frequent attempts on their own lives and those of others. For the most part the orientation of the patients is unimpaired. Usually they comprehend clearly where they are, reckon time correctly, and do not fail in the recognition of their acquaintances. Along with the orientation we can say that the perception of internal impressions and consciousness are not seriously impaired. They understand thoroughly all that happens to them and everything that goes on about them, even when they appear the most stupid. Some patients also seem to retain all their mental faculties in periods of great excitement and activity. After the onset of the disease, in the majority of cases, there is a rapid decline into the depressed state, in which it may be said the symptoms become more prominent and pronounced. In this state orientation frequently suffers and is decidedly impaired by delusions. Brownrigg[2] says that the difficulty is not in the inability of the patient to perceive or reflect rightly, but it is because the morbid and false perceptions are more persistent and insistent than the true perceptions. The patients undoubtedly acquire these delusions as a result of various hallucinations which present themselves. These hallucinations are of many kinds and descriptions. They often diminish gradually as the disease progresses, and reappear again in the last stages. In some cases, however, they are persistent throughout the entire disease. The hallucinations are most frequently those of hearing, and following these, and occurring less frequently, are hallucinations of sight and feeling. Very often the hallucinations are of a disagreeable character, and the patients are apt to become depressed and suspicious as a result of them. The delusions which accompany the hallucinations of this kind are, of course, of the same type. The patients imagine that they have committed most atrocious crimes, that they are unworthy and unfit to live, etc. In this state they frequently manifest suicidal tendencies. Kraepelin speaks of the augmentation of these various delusions by fabrications. The patients claim to be persons of distinction and control, and that they are antagonized on this account. In nearly all cases the judgment is greatly impaired. Great difficulties are encountered when these individuals are called upon for some decision. There is most always difficulty in comprehension, and a distorted conception of the exact surroundings. The train of thought is also disturbed. The expressions of the patients seem to be disconnected, and this condition progresses with the disease leading up in some cases to a complete incoherency and confusion of speech. In many cases the train of thought gives evidences of stereotypy, the patients using certain rhythmic, meaningless, and peculiar expressions continually in their speech.

Memory is progressively deteriorated. At the onset of the disease patients usually can give their past history very accurately, and the knowledge gained in school seems to be held very tenaciously. The disease does not progress far without marked deterioration being noticed. There is especially loss of memory for recent events in the excited or stuporous condition. The attention is usually greatly impaired in all stages of the disease. With difficulty the patient's mind is held on any subject for even a very short period. Every interest in the subject rapidly disappears, and there is a relapse into the former state. In the most advanced stages it is impossible to arouse any active attention. The patients do not attempt to learn or comprehend anything in this state, notwithstanding the fact that the perceptive powers are not always markedly impaired. The disposition of the patients, and with this the emotional life, suffer quite serious changes. At the onset of the disease we frequently see a sad, anxious, and careworn expression upon the patients, indicative of a depressed mood. Paroxysmal laughter and crying alternately is not infrequent. Later the patients usually become apathetic, and utterly devoid of all emotions. They lose all affection for relatives and friends, and experience no change of feelings within themselves, no matter how great the stimulus may be. Not infrequently we find a morbid expression of the religious or sexual life, usually leading to excesses along these lines. In cases where these morbid feelings occur they are usually found in the early stage of the psychosis, and generally disappear as the disease progresses.

In this class of cases we usually note a marked change in the power of will or volition, and in the latter stages it most always entirely disappears. With a change in the will power we, of course, expect a corresponding change in conduct and action. There is usually a decline in all ambition and desire to be active. The patients are usually idle, neglect their personal appearance and obligations to others. They are in general hypersuggestible, although frequently excitable and untractable. In the excited periods the hebephrenic is liable to perform all sorts of impulsive acts. There is frequently an inability to express the sudden impulses on account of other impulses which are stronger, developing and overpowering the weaker ones. In this way the symptom of negativism develops, which is more characteristic of katatonia, and will be considered fully under that form of dementia præcox.

Katatonic Form.—This form of the disease is characterized, according to Kraepelin, by a peculiar condition of stupor with negativism, automatism, and muscular tension; excitement with stereotypy, verbigerations, echolalia, leading in most cases with or without remissions to a condition of mental deterioration. The onset of this form is not unlike that of the depressed type of hebephrenia. The patients are usually noticed to be quiet and seclusive for some time before the direct onset of the psychosis. The same difficulties of thought are prominent symptoms, as is the anorexia, cephalgia, and general nervousness found in hebephrenia. It may be said that the clouding of consciousness is more marked and the perception of internal impressions is more impaired earlier in the disease than in hebephrenia. Consequently, the patients become disorientated sooner than in the hebephrenic type.

The judgment is of course much impaired, as is the train of thought. There is a decided amount of incoherency and disconnection in the speech of this class of patients. It is with difficulty that the attention can be held for any length of time. Memory suffers about the same changes as in hebephrenia. In the latter stages of the disease there usually comes a complete cessation of the psychic function, and consequently there is a complete inhibition of all thought. Early in this form of the disease hallucinations appear with their customary delusions. Kraepelin thinks that the delusions are usually of a religious nature, but the experience in the majority of American hospitals does not substantiate this

assumption. While a great many of the delusions are religious in character, it cannot be said that they are in predominance, for many others of widely different character are equally prominent. We find the emotions in decided harmony with the hallucinations and delusions.

During the period of depression which follows or occurs at the onset of this form of the psychosis there develops a series of conditions which are most characteristic. The first of which we will speak is katatonic stupor, and the symptom most prominent in this stupor is negativism. As we said in considering hebephrenia, negativism results in the inability to express certain voluntary impulses on account of their being overpowered by stronger impulses, which are inhibitory in character. This strange condition is easily demonstrated in certain patients; they begin to act readily, but these voluntary impulses are not strong enough to resist others which arise, and the patient does exactly the opposite of the thing desired or asked. Some of the impulses are those which are most natural and to which the patient is most accustomed. They shut their eyes when told to open them, and conversely; they refuse food when it is offered to them; they object to changing their position, etc. Their actions appear to the casual observer as pure stubbornness. All active attention is inhibited by negativism, as is seen by the patients, developing the attentive attitude when the negativism is gradually disappearing.

External impulses do not often affect the symptom, negativism. It is certain internal impulses interrupting the natural impulses which move the patients to arouse suddenly from their stupor and commit some act. As is oftentimes the case, these internal impulses are persistent, and they frequently repeat themselves, causing in these patients what is known as stereotypy, a condition in which the movements and attitudes of the patients are always performed in the same manner, and, as it were, become stereotyped. Stereotypy with impulsive action characterize katatonic excitement, which usually follows the stuporous condition. Along with the stereotypy in these cases can be mentioned the mannerisms of speech and facial expression and the verbigerations most common in this form of the disease. The every attitude of the patients, their gait, writing, speech, etc., portray the action of the internal impulses which are continually interrupting the natural impulses.

In the condition of katatonic excitement, owing to the serious impairment of the volitionary impulses and the inability of the natural impulses to inhibit correctly, there develops a condition known as automatism. In this condition, as the name implies, the actions of the patients are automatic, and this, together with the stereotypy, presents a very interesting combination of symptoms.

A large majority of these cases also exhibit echolalia and echopraxia at some period during the condition of katatonic excitement. The patients act readily on the suggestions of others, and perform the routine duties of the ward in a willing manner. There seems to be a heightened susceptibility of the will in these cases, and especially in those where the mind has become very much deteriorated.

Paranoid Form.—This type of dementia præcox is made to include two types of cases, one in which the hallucinations and delusions are incoherent, and the other in which there is a decided coherency. These delusions usually persist for years, notwithstanding the fact that they are attended with gradual mental deterioration. Kraepelin distinguishes the delusions and hallucinations of the paranoid form from the hebephrenic and katatonic forms, in that in the last named forms the delusions and hallucinations disappear as the deterioration progresses, while in the paranoid form such is not the case. He makes the distinction between the paranoid form and true paranoia in that in the former form the onset is usually more acute, and accompanied by other symptoms of dementia præcox, and the mental deterioration is more rapid than in paranoia.

In the first class of cases the patient usually has two kinds of delusions, those of persecution and those of grandeur. They are decidedly incoherent and changeable. They are attended by a slight degree of motor excitement and deterioration of mind. The hallucinations which accompany, and the delusions, are usually of hearing. Patients imagine, when they hear the sound of voices, that the conversation is relative to themselves, and they frequently become fearful, agitated, and quite emotional. In the early stages of the disease there is no clouding of consciousness or disorientation. During the later stages there is gradual impairment of these qualities. The capacity for mental work is considerably lessened, although some patients are able to perform certain mechanical tasks under the supervision of others. In general the patients are exalted, irritable, and loquacious. The train of thought based upon the morbid delusions is, of course, incoherent, although questions relative to the delusions may be answered coherently and relevantly. Memory for past events is nearly always good, while that for recent events is somewhat impaired. The powers of attention and volition suffer gradual impairment as the mental deterioration advances.

In the second class of cases we find the same delusions of grandeur and persecution, but they are in most respects quite coherent. The delusions are often expansive, taking the form of those found in dementia paralytica. In this class, as in the first, the hallucinations are of hearing, and are intimately connected with the delusions. The persecutory and expansive delusions are more gradual in their development than those of the previous class.

The consciousness and train of thought remain unimpaired in the majority of cases. There is some slight disturbance of the emotional life, the patients usually in the first stages being depressed, and later quite cheerful and ecstatic. Kraepelin speaks of the ideas of spirit possession being prominent characteristics in some cases.

Physical Symptomatology. The physical symptoms of the three types of dementia præcox will be considered together briefly. The most prominent symptom of this psychosis is found in the general disorder of nutrition. There is usually some disturbance of the vasomotor system which may cause blushing, cyanosis, bromidrosis, and hyperidrosis in some cases, and all degrees of dermatographia. The cardiac action is usually impaired, producing irregular, accelerated, or retarded movements. The patients frequently lose in weight and suffer with anorexia, intense headache, and insomnia. There is an amenorrhœa in certain cases, together with a complete cessation of sexual desire. In a large percentage of cases in the latter stages of the disease there is a partial return to the normal, the patients increasing in flesh; the heart action improves; the appetite returns, and sometimes becomes excessive. This condition, however, is usually quite transient, and many of the body functions fluctuate as the disease progresses. Kahlbaum and Jensen describe convulsions of the epileptiform and fainting types occurring in dementia præcox, also cramps

and tetanic contracture of certain groups of muscles; apoplectiform convulsions with combined paralysis, etc. Kraepelin thinks these attacks occur in about eighteen per cent. of all cases. He also speaks of hysterical convulsions and paralysis, aphonia, hiccough, and certain choreiform movements, which he designates as "athetoid ataxia."

The pupils are usually dilated, but react readily. The deep and superficial reflexes are exaggerated, and there is an increased excitability of nerves and muscles. A state of increased muscular tension sometimes exists in katatonic stupor. This condition is frequently attendant to negativism of the body functions such as the retention of urine and feces, and some authors regard this as a partial cause of the increased tension. There occurs in this stage of increased tension frequently a uniform position of the body or the parts, which in some patients is very difficult to change. They often remain in this characteristic position for long periods, only changing it when compelled to do so. When there is less muscular tension there often exists a condition known as "cerea flexibilitas," in which the patient can be changed into any position, whether uncomfortable or not, and will remain in this position indefinitely.

In a good many cases of dementia præcox there is an increase in salivary excretion. In one katatonic patient, to my knowledge, 200 c.c. have been collected in three hours. Kraepelin reports a case in which 375 c.c. were collected in six hours.

The temperature is in most cases subnormal, but in some cases of excitement it has been known to rise to 102 degrees.

Prognosis.—Dementia præcox runs a very progressive course, and usually ends, with few exceptions, in mental deterioration and apathy. The course in the hebephrenic form is frequently interrupted by great improvement in the patient's condition and partial return to the normal state. The degeneration, however, usually progresses more rapidly when a remission occurs. The disease runs a course lasting in most cases for years. The profound states of dementia are sometimes reached in from eighteen to twenty-four months after the onset of the disease, but in most cases the length of time is much longer. In hebephrenia there are often short periods of increased excitability, incoherence of thought, clouding of consciousness, irritability, aggressiveness, etc., lasting for an hour or more, and then subsiding. In katatonia there is usually the period of depression, followed by the period of excitement leading on to mental deterioration. Sometimes the period of excitemnet does not occur, and the patient passes from the stupor into the demented state. The katatonic usually succumbs as a result of some intercurrent disease, and not from the psychosis direct.

In the paranoid forms the course is progressive, and is characterized by the absence of remissions. As the disease progresses the mental deterioration becomes more marked, and the patients gradually become disorientated and incoherent in thought, leaving them completely incapacitated for mental work.

In giving statistics, we quote in the main from Kraepelin. In hebephrenia, seventy-five per cent. of the cases reach a state of profound dementia; seventeen per cent. of cases reach a state of deterioration not so far advanced, and eight per cent. of cases are cured. In katatonia, eighty-six per cent. of cases end in mental deterioration of different stages, and about fourteen per cent. seem to recover. In the paranoid form, the outcome, according to Kraepelin, is always deterioration.

It can be said that dementia præcox never terminates fatally. Those afflicted with this psychosis usually die as a result of some other disease.

Etiology.—The etiology of dementia præcox has not as yet been definitely established in every particular, but a few facts can be said to have been accepted. Kraepelin says that more than sixty per cent. of the cases appear before the twenty-fifth year. When we consider the various forms we find a still wider variation. In the hebephrenic form almost seventy-five per cent. of cases appear before the twenty-fifth year. In katatonia we find a still smaller number, only sixty-eight per cent., and in the paranoid form only forty per cent. appear before the twenty-fifth year. The hebephrenic form is most prevalent (Kraepelin, sixty-four per cent.) among males, and in the paranoid and katatonic forms the females are said to predominate.

The most causative factor of this disease of early life seems to be a defective and deficient heredity. We find in nearly all patients of this class a constitution which is distinctly neurotic, and this condition to be due undoubtedly to a similar constitution in the patients' ancestry. We have an unstable nervous system of this kind subjected to severe strains and stresses either of mental or physical nature, and we have a psychosis produced due to the exhaustion of the nervous system. This condition in the majority of cases is typical of dementia præcox. These strains and stresses in a large number of cases come on at pubescence when the sexual functions are becoming prominent and most frequently result in excessive sexual indulgence. At this period, and the years following, the body is more susceptible to both mental and physical overwork, and we frequently find this peculiar psychosis developing as a result.

Certain febrile diseases, such as scarlet fever and typhoid fever, are sometimes etiological factors. Peterson[3] gives frequent child-bearing as sometimes a cause. Frequently we find the psychosis developing after the birth of the first child. A case of this kind is reported under the metabolism work on dementia præcox done by the author.[4]

Brain trauma and hemorrhages may be said to be the cause of a small percentage of cases, also the excessive use of alcohol and drugs, which affect the metabolism of the nerve cells directly.

Pathology.—In regard to the pathology of dementia præcox there is still some doubt. Some authors regard it as a purely functional psychosis, while others give it a definite pathological basis. That there is a lesion in the brain cortex seems quite probable, judging from the clinical course of the disease. The fact that a small percentage of cases are cured is indicative of a brain lesion, which is sometimes capable of being repaired. Kraepelin, in his Clinical Psychiatry, reports the findings of Alzheimer in a case of acute delirium, which he classed with katatonia. He found the nucleus swollen and its membrane wrinkled, the cell body shrunken, the neuroglia fibers increased and attached to the cell in a peculiar manner. He reports also a displacement of the neuroglia cells, very large ones being found in the deeper, instead of the superficial layers of the cortex.

The theory of autointoxication has been given some consideration. This is due to the intimate connection of some cases of the psychosis with pubescence, pregnancy, pueperium, disturbance of the menstrual function etc.

That there is a marked change in the nutritive

processes are to be regarded as primary conditions causing a neurotrophiosthenia which produces this psychosis, or whether they are to be regarded as secondary to the mental disturbance, is a question to be proven. What the changes in the nutrition are has not been thoroughly investigated, and the causes of these changes and the results of them still remain an unsettled problem.

PES PLANUS FROM THE VIEWPOINT OF NEUROLOGY.*

By CHARLES P. FRISCHBIER, M.D.,

BROOKLYN, NEW YORK.

THE relatively large number of cases coming to the clinic of Prof. Collins at the New York Post-Graduate Hospital for the relief of pains in various parts of the body, in whom after careful examination flatfoot or weakfoot is found as the sole attributable source of such pain, has led me to believe that the discussion of this subject might be profitable.

Although the pain of flatfoot is usually of the feet and legs, it may be of any part of the body, for I have seen improvements of flatfoot in most instances followed by a cessation, or at least amelioration of aches and pains in remote parts. From an analysis of 125 cases, I feel justified in regarding congenital or acquired weak and flatfoot a source of irritation capable of causing widely-scattered pains and discomfort to the degree of depression and exhaustion in particularly susceptible subjects. In all cases and all degrees of flatfoot we naturally expect to find local pain or tenderness about the foot, ankle, or leg, and these sensory disturbances frequently are not commensurate with the development of deformity, so that in the beginning destruction of the joint, long before any noticeable change of outline, the pains are apt to be most severe and continuous. Quite frequently also the pains appear localized at first about the knee or hip joints, and later travel downward to concentrate themselves about the member at fault. In 50 cases pains extended to the thighs; in 47 there was great pain in buttocks and lumbar region; in 39 the pain was first felt in hips, thighs (anteriorly), and inguinal region; in 34 cases there was backache up to the shoulder blades; in 21 extreme general irritation, followed by depression; in 17 there was pain in back, also right or left arm; in 4 cases there were restlessness, insomnia, pains worse at night in opposition to the general rule that resting the feet relieves pain.

The dysesthesias were variously described as pressure constriction, numbness, dull ache, or pains of shooting, stabbing, pulling, or throbbing character. The extremely ingenious method of taking an impression of the feet upon specially prepared paper by means of the ferrocyanide of iron reaction having failed so often to reveal deformity, simply because of the insidious joint change residing only in the upper parts, we must rely upon the following:

1. Other causes being excluded, increase of pain on active and passive manipulation of the joint, on standing particularly, on walking, jumping; tenderness on pressure over some or all the bony prominences, as the scaphoid, metatarsal heads, os calcis, etc., and impaired mobility of the ankle joint somewhat impeding adduction, limiting extension, and causing a feeling of constriction or weakness of the joint, point to weakfoot, beginning flatfoot.

2. More advanced cases present greater prominence of the internal malleolus and astragalus, with corresponding depression or gradual effacement of the fibular landmarks. Weakness is more pronounced at the inner side of the foot and ankle; there are strain and ache of these parts and the calves. Coldness, numbness, hyperidrosis, all aggravated by atmospheric changes, are noticed. Discomfort and tire after short walks necessitate frequent rests, during which the joint components partially reposit themselves in the normal order, shortly after again to be jarred and jounced, and stretched apart, so as to cause renewed and increased torture. The patients become more or less awkward in their gait, watch their footing more in order to avoid rough or uneven places (cobblestone pavements, ruts, obstacles), feel less secure on their feet, use their heels more than their toes, and wear away the inner side of the sole of the shoe.

3. When the deformity has become evident the gait and station may change to an actual wobbling, limping, or staggering, and slight efforts of the pedal extremity may require such an excess expenditure of energy and force as to tempt the patient to remain inactive, or at least to save locomotion. As above mentioned, the pains usually are not so severe in this stage, being replaced by a transient dull ache.

Let us recall that the arch of the foot is formed in a longitudinal direction by the oscalcis, and the posterior part of the astragalus as its shorter, posterior limb, while the rest of the tarsus and the five metatarsals may be regarded as constituting its longer anterior portion. The junction of these, the calcaneocuboid and the astragaloscaphoid articulations, is made more stable and useful by a number of ligaments, the calcaneonavicular ligament particularly being considered one of the strongest and most resilient in the body. The summit of the arch is the articular surface of the astragalus, which supports the tibia and fibula. Transversely from within outward a half arch is formed by the gradual downward slope of the central portion of the foot till its outer border rests upon the ground. The fundament or base of these arcs is composed of the tubercles of the oscalcis posteriorly and the metatarsal heads anteriorly.

The action of the foot is that of a lever of the second order. In normal walking the weight of the body is lifted by the calf muscles, the power, acting upon the metatarsal heads as the fulcrum. To use this power properly and economically the relation of the foot to the leg should be that of a plane passing through the center of the knee and ankle joints to the center of the foot anteriorly, *i.e.*, the second toe. Thus the forefoot, in lifting over the fulcrum, is slightly adducted, so that a degree of intoeing and parallel action of the feet is natural and normal, and is seen in all primitive people and those who walk barefooted. Outward rotation (abduction) of the feet, as taught civilized people, and practised to an extreme in armies, is unnatural, not hygienic, and should be condemned. In weightbearing, while standing, the feet are normally abducted, and the internal malleolus seems to slide downward, because of slight inward displacement of the astragalus. This latter, the passive weightbearing, not walking, attitude is assumed by the weak or flatfoot, and may be called a fairly constant, early symptom.

*Read before the Brooklyn Neurological Society, October 25, 1906.

When the arch is originally low, or of congenitally weak, bony development, as is apt to be the case in the rachitic, tuberculous, or so-called scrofulous type of subjects, considerable deformity may exist without pain or disability, due to early accommodation of the readily-yielding components. In the beginning collapse of the arch, the astragalus and scaphoid are lowered and rotated inward: this is followed by a settling of the internal border of the oscalcis and a depression of its anterior extremity. This may progress to such a degree of dislocation as finally to cause the entire inner sole to rest upon the ground, producing a callosity.

The anterior and post-tibial nerves, directly supplying sensation and motion to the ankle joint and tarsus, will be the first, we may assume, to respond to the irritation caused by the gradual continuous change. In many, in fact at least 45 per cent. of these cases, there is not only no localization of painful sensations in the lower parts, but even a high degree of radiation, as above described, so that one may infer a spreading or referring of pain by way of the branches of the sacral and lumbar plexuses, which would perhaps account for symptoms felt in the regions of these cord-levels. Pains in the upper parts of the back, trunk, and arms may possibly be interpreted as due to strain in favoring the impaired limb by postural measures, thus further disturbing the equilibrium eventually. It must also be borne in mind that a great number of these patients are neurotics, or otherwise physically below par, so that even mild stimulation is reacted to excessively and extensively.

The ages of the individuals examined varied between 16 and 64 years; the majority were in the second and third decade. The duration of the trouble, counting from the time of beginning pains in the feet or legs, was from one month to ten years. 85 per cent. of the cases being of the acute or subacute form. The occupations represented here agree well with those commonly cited as favoring the development of weak or flatfoot, *i.e.* (1) those requiring much standing, particularly when limited to a confined space (waiters, salesmen); (2) conditions resulting in a weakening of structure from comparative disuse, those of sedentary habits especially, with limbs in cramped positions, as tailors, squatting on tables; (3) those calling for an excess of work with consequent weakening, as in agents, canvassers, and letter-carriers. To this latter class may be added the large number of sewing-machine (foot-power) operators, largely represented at this clinic by the lower East Side Hebrews, some of whom were at work before their fourteenth year, turning the wheel eight or ten hours daily.

Treatment.—Foremost is rest in the horizontal position, to relieve the feet and legs of all strain; passive and active manipulation of the parts, electricity, baths, and massage aid in eliminating inflammation. Fixation of the feet for a certain period of time in a position of flexion, inversion, and adduction by means of strapping, bandaging, or in bad cases plaster casts, is beneficial. In extreme cases surgical measures may be necessary to secure restoration of function. Unfortunately, the majority of our patients cannot afford this more thorough, but slow, rest treatment, being compelled to earn their daily bread; they ask relief to enable them to continue their avocation.

Here the much vaunted arch supporters and braces made of metal, leather, or hard rubber were found on actual trial not to sustain the reputation they undeservedly bear, unless properly fitted by the orthopedist.

The wage-earner is best served by shoes constructed on scientific principles—broad, substantial, roomy, with stiff counters and built-up soles and heels. Exercises carefully adapted to individual needs, such as balancing on tiptoe, moderate dancing, alternately raising the body on the toes or heels, and inverting the feet are of great value.

1228 Putnam Avenue

THE HYOSCINE SLEEP IN OBSTETRIC PRACTICE.

By WOODBRIDGE HALL BIRCHMORE, M.D.,

BROOKLYN, NEW YORK.

Since the rediscovery of the conditions under which the deep sleep, resembling death in its soundness, of which the tradition had come down through the ages, could be produced, men in various parts of the world have made use of it to obtain insensibility to pain. A few have made use of it in the practice of the obstetric art, and some have furnished to me notes more or less complete of their experiences. From their notes I have gathered certain facts which I have used to form the material for this thesis, which may be considered, I believe, as a statement of the conditions in fact and in practice, on which that great improvement in the obstetric art for which we have long been looking, may reasonably be grounded.

The actual results which have been attained may be summarily stated in very few words; the patient slept, labor came on, and progressed in accord with usual conditions, normally in relation to the details. The labor was not prolonged, far otherwise, and in no case was it needful to use an anesthetic, although the forceps was used thrice. The only case in which the mother showed any signs of awakening was not one demanding interference. No results influencing the infant unfavorably were observed, although most anxiously looked for. Such is a summary of the results, but that this summary may be duly appreciated it is well to consider the whole proposition, theorem, and demonstration in detail. The hyoscine was administered hypodermically in doses of 1-100 grain, in combination with morphine, 1-4 grain, and cactin 1-67 grain. This amount was given in solution in 1 c.c. of water, and repeated as required. Much stress is laid upon the absolute purity of the ingredients for reasons which are obvious, but it is of special moment when so small a dose as that of the hyoscine is used that the nearest possible to absolute purity should be attained.

As a rule, the remedy was given hypodermically, but in one instance the first dose was given per os, and, except for a delay in taking effect, no change from the normal was seen. The first dose was given as soon as the first stage of labor was certainly begun, and was in most cases sufficient to hold the patient until the so-called expulsive pains were distinctly pronounced. The instant the patient began to show the least evidence of perception, the second dose was given. In the cases requiring the aid of the forceps a third dose was given in two instances, but not in the third case, and probably the second forceps case did not really need the third injection.

The effect upon the patient does not show the variation which might in some sense have been expected, so far as the depth of the sleep and the length of it is concerned, nor did the doses have the cumulative effect which might have been expected. On the question of the length of the nap one group of cases suggests six hours as the normal duration, while another group gives eight hours from the time the second dose was given. But in the case in which there was an eight-hours' sleep,

the time between the two doses was less than in those in which the sleep was for six hours. The exact relation between the doses and the length of the nap is still very indeterminate.

In one instance only was any effect upon the unborn child alleged. In this case the os uteri was dilating, but slowly; and, as the woman complained of the exceeding severity of the "cutting and tearing pains," the physician gave the hyoscine by the mouth rather sooner than the apparently best practice, when the intention is to give the second dose as soon as true labor begins. The mother had repeatedly declared that "this child kicks something awful," and continued to complain for at least four hours after the dose was given, at which time she was becoming drowsy. She was soon fully under the influence of the drug, the unsatisfactory pains of the first stage continuing until she was fully asleep; after this they rapidly improved. The woman slept only five hours, and when she awoke the os uteri was still undilated. The pains continued after she awakened in about the same force as during her sleep, but she suffered much less than before her nap. She now noted that the child had ceased to kick, and it was some hours before "the boy recommenced his exercise, which he did gradually, and continued to cause discomfort as long as he was able." The words are his mother's, who, in describing the sensation, said: "If he is such a kicker all his life he will make lots of trouble." The os uteri was not fully dilated until well on in the evening, and the mother having received a second injection at the beginning of real labor slept until after the birth of her child, becoming somewhat restless at the end, but not regaining consciousness until after the baby had been cared for and all provisions made for the comfort of the mother. In one other case there was strong evidence that the baby was put to sleep, but in neither case is it proper to regard the fact as actually proven. All direct evidence of long-continued interference with the actions of the child after birth is wanting, and in only one instance was any effect positively affirmed by the physician attending.

Apart from the influence upon the direct progress of the labor, the effect upon the mother was most noteworthy, first as quite hindering the mental disturbance which pain and suffering in all cases produce. The effect was fully covered by a remark made by one who used it: "Objectively, as evidenced by the mother's condition, it appeared a preposterous proposition to say that she had given birth to a child." The mother shows no signs of exhaustion, and although the resistance (passive) of the tissues must be quite the same, it can be clearly seen that no spasmodic resistance, by inhibition due to pain, in any way interferes. This absence of the inhibitory (active) resistance is perhaps the most remarkable effect produced. One woman whose labors had been notably tedious was delivered of her fourth and largest baby in less than two-thirds the time of the shortest of her previous experiences, and in one-third the time of her longest. She had always been notably restless and hard to manage, but in this case she simply slept through the whole series of phenomena; she did not awaken until she had been removed into a clean bed and provided with all things needful. At the birth of the head, although soundly sleeping, she made certain spasmodic actions and changes of position which caused some surprise to the nurse and attending physician. Although the attending physician described them as carefully as possible, the intention of his words is not clear enough to my mind to justify any attempt to repeat the account, but the conviction is forced upon me, as it were, that the physician's two statements, "Her actions showed that certain combined movements should occur which are inhibited in the large majority of cases," and "It was as if I had seen the natural action of a woman for the first time," really contained an important truth.

If an attempt is made to describe the phenomena from the time when the patient falls asleep in the first stage of labor to the end of the slumber, it must be admitted that the remarkable character of the phenomena is too plain to be missed. If Byron Robinson's theories are accepted in full, and we regard the action of the muscles usually controlled by the cerebrospinal system, we cannot but wonder at and question how the coordination is maintained. In two cases the woman rolled onto the left side, partially flexed the left leg upon the thigh, and the thigh upon the pelvis, so that the child was, or rather would have been, supported and guided onto its back by the act of extrusion. The right lower extremity extended to the extreme, the toes pressed against the foot of the bed, gave a "fixed point" for the muscular leverage.

In the majority of cases the heels were brought up close against the buttocks, and in these cases the muscles were made tense, lifting the buttocks completely off the mattress at the instant of the birth of the head, yet there was no sign of awakening. The steady, slowly increasing, and tremendous force exerted by the abdominal muscles during the expulsive pains, attracted the attention of all observers. One who has seen great numbers of labors said that he never saw anything like it before, and added, in an extended opinion, that the great advantage over chloroform is easily seen in that, with the hyoscine sleep, reflexes are greatly augmented, not suppressed.

All who have made use of hyoscine a few times appear to regard this restoration of the truly natural conditions as being of almost as much importance as the unconsciousness from sleep. "If we use hyoscine the mother cannot do mischief by her own excited and voluntary or semivoluntary actions," is a remark made by every user.

It appears probable at first sight that there must be greatly increased danger of perineal rupture, and I so suggested to some whom I was able to question. All of them said that proof of this proposition was wanting, and one man said: "I am quite sure that you are wrong in this opinion, for the rupture of the perineum, when not due to the haste of the accoucheur, is due to the excitement of the mother. From what I have seen I am inclined to regard the dilatation of the perineum much as I regard the dilatation of the os uteri. It is gradual, and the obstruction, although usually needless now, must have been of importance once. The waking mother makes convulsive efforts to overcome the resistance of the perineum, and when she feels the obstruction has a titanic, if not a tetanic spasm, to force the head by, and then the shoulder catches. But in the hyoscine sleep the first perineal pains are not convulsive, and, instead of two or three ineffectual attempts ending in an almost convulsion, the sleeping woman has a dozen small pains gradually stretching the sphincter, and, beside this, the head is not held so firmly against the sphincter, or rather against the fold of submucus tendon, that this cannot roll; and after once or twice trying the whole apparatus—tendon, muscles, and mucous membrane—slips out of the way, and the last expulsive pain comes on. For my part, I regard this use of hyoscine as important because it has restored the conditions of natural labor: I know my expression is bad, but somehow hyoscine gives the management of labor back to the reflex

ganglia from which the brain had, in women, taken it away."

Naturally, the objection is made that in some ways this theory proves too much; that in the apes the difference in position made the perineum a less important organ, but this objection is countered by saying that we really know but little of labor in the highest apes, and nothing of what it may have been in other—the simio—human race. "Anyway, in the hyoscine sleep the 'perineal pains' are more orderly," insisted this physician.

In the cases referred to in which the use of the forceps was judged to be needful, the cases in no way differed from others of their kind in which a more transient insensibility is obtained by the employment of familiar anesthetics, but owing to the activity of the natural forces of parturition the delivery in fact rather suggested the use of the forceps in the conscious woman's behalf than in that of the unconscious one. No special details or unusual reasons for the use are recorded. Certainly the use had no connection with the insensibility of the patient. One or two suggestive facts were mentioned in this connection, as if the accoucheurs had in their minds a strong suspicion, amounting almost to a convinced opinion, that the conditions of the use of the forceps would be found to differ, and perhaps to differ profoundly, from the cause, which is by many believed to be the cause most frequently demanding the use, namely the threatened exhaustion of the mother. This because all who have made use of this narcotic, without any exception, insist that exhaustion, even to a small degree, is hardly to be perceived. The absence of excitement, the regularity, and above all the maturity of the expulsive efforts, the fact that none of the vitality of the mother is expended in useless and exhausting, because ineffectual and disorderly efforts, promises to lessen greatly surgical interference, the special interference demanded by the mother's exhausted state.

Speculations and Conclusions.—Such data as are given here must be regarded only as so many facts, observed by competent and experienced men indeed, but considered simply as facts they are quite barren of usefulness, for it is only when we consider them as the data to be examined by logical processes that they, becoming living and productive, are the foundation on which we can erect a useful theoretical structure.

In the first place, the importance of the hyoscine sleep in obstetric practice is amply demonstrated, and experience shows that it can give us all the aid in quieting the patient that any narcotic can give, and in addition it gives us a practical anesthesia of prolonged duration, and gives this anesthesia without risk to either mother or child. Further than this, we have the most abundant proof that this practically anesthetic sleep is quite without danger because the respiratory system is in no way interfered with, nor is the heart's action restrained. It is also clear that the reflex actions which find their point of departure peripherally and return to the periphery again from spinal and sympathetic system ganglia, specifically from the "pelvic brain" of Byron Robinson, are not restrained, but rather they are augmented by the action of this drug. Clearly, then, it is a drug sedative to the cerebrospinal axis, but not to the ganglia connected with the reflexes of common life.

This fact alone is of no trifling importance, but the import grows when we note that in shutting the door, so to say, to the influence of all the inhibitory actions, it leaves quite unopposed the influence of the sympathetic system, and the physician using it need have no fear of any accidents to disturb the normal evolution of a birth.

It is, then, for the accoucheur the ideal anesthetic, one which so far as we yet know he can use to obtain the desired effect without fear of an overdose. So far as I have been able to learn no one has yet had any experience with an excessive dose. Until this excessive dose shall have been given our information remains in a sense defective, but we certainly know that all we need to give can be given without risk or danger.

Finally, and perhaps of all the most important, this use of hyoscine has stripped motherhood of its horrors. The dread of pain has been the great dread of the coming birth; until this discovery the "pains of maternity" remained a horrid and incontestible truth, but these have vanished and the exhausting ordeal of motherhood is gone, to be seen no more.

163 Fulton Street.

WORKING FORMULÆ TO FACILITATE THE PERCENTAGE MODIFICATION OF MILK.

By CHARLES J. DILLON, M.D.,
NEW YORK.
CLINICAL ASSISTANT, DEPARTMENT OF PEDIATRICS, BELLEVUE AND UNIVERSITY MEDICAL SCHOOL.

The percentage modification of cow's milk now so generally used for the feeding of infants has brought with it a plague of petty mathematics, from which the practitioner is wont to shelter in the kindly and accommodating "round number," and accuracy is sacrificed to convenience.

Accuracy is a very desirable quality in milk modification, and the following contracted formulæ, while simple, will certainly be found serviceable in this respect. They are simple enough to be remembered, but perhaps a better plan would be to have them on a card for easy reference. They are designed for the rapid and accurate determination, for a definite quantity of a given modification, (I.) of the percentage cream necessary for dilution, (II.) of the quantity of the cream required, and finally (III.) of the quantity of gravity, or 16 per cent. cream required, which when diluted with whole milk will give a percentage cream as determined by I., and to the quantity determined by II.

Rule I.—The fat percentage (f) of the modification multiplied by 4 and divided by the proteid percentage (p) of the modification will give the fat percentage of the cream required for dilution, or, graphically: $\frac{f \times 4}{p}$ = fat percentage of cream required.

Rule II.—The total quantity in ounces (n) of the modification multiplied by the proteid percentage (p) and divided by 4, will give the ounces of cream required for dilution: $\frac{n \times p}{4}$ = ounces of cream required.

Rule III.—To determine the quantity of 16 per cent. cream required to make, with a proper quantity of milk, a desired quantity (N) of cream of a stated fat percentage (F): $\frac{N\,(F-4)}{12}$ = ounces of 16 per cent. cream required.

To make an application of these rules we will suppose that we require 48 ounces of a 4-7-2 modification.

By Rule I. $\frac{f \times 4}{p}$ = percentage cream required, in this case $\frac{4 \times 4}{2} = \frac{16}{2} = 8$ per cent. cream.

By Rule II. $\frac{n \times p}{4}$ = quantity of 8 per cent. cream, in this case $\frac{48 \times 2}{4} = \frac{96}{4} = 24$ ounces.

Having ascertained by the two previous equations the quantity and fat percentage of the cream required, 24 ounces of 8 per cent. cream, we have still to derive that cream from the gravity cream, and, by Rule III.,

$\frac{N\ (F-4)}{12}$ = quantity of 16 per cent. cream required, in this case $\frac{24\ (8-4)}{12} = \frac{96}{12} = 8$ ounces, 16 per cent. cream. Here we have quickly and accurately determined that, to make 48 ounces of a 4-7-2 modification, we require 24 ounces of 8 per cent. cream, or its equivalent, 8 ounces of 16 per cent. cream, and 16 ounces of whole milk.

Of course one can see at a glance the percentage cream and quantities necessary for a 4-7-2 modification, but in many cases they are not so obvious, and in these the formulæ will be found particularly advantageous.

Contracted for easy reference, the formulæ would be as follows:

I. $\frac{f \times 4}{p}$ = fat percentage of cream required to make a *modification* with fat at f per cent.

II. $\frac{n \times p}{4}$ = quantity in ounces of cream required to make n ounces of *modification*.

In Rule I. and II. p is the proteid percentage of the *modification*.

III. $\frac{N\ (F-4)}{12}$ = quantity of 16 per cent. cream required to make N quantity of cream with a fat percentage of F.

Since Rule III. is based on a general formula for the reduction of a cream of a certain fat percentage to one of a lower fat percentage, those who use a 12 per cent. cream for their modifications may modify Rule III. for 12 per cent. cream as follows:

$\frac{N\ (F-4)}{8}$ = quantity of 12 per cent. cream required to make N ounces of cream of a fat percentage of F.

206 West Ninety-fifth Street.

Poison Ivy.—A. Hadden has observed that, if the skin is moist from perspiration, the poison of rhus is more apt to take effect than when the skin is dry. The poison is more active during the summer months and the last two months of spring and the first two months of autumn. It does not seem to be active during the other months of the year. The nature of this poison has not yet been clearly defined. On the leaf and stem of this vine there is a fine, hairy formation on both the upper and lower sides. To this is attributed the chief agency of communication of the poison. Both flies and mosquitos are doubtless the carriers of these small, hairy particles as well as of the sap to many sensitive skins. It is doubtless these insects instead of the innocent breezes which carry this poison. The writer advises those with skins sensitive to the poison to wear veils and gloves when in the vicinity of the vine. He has had the greatest success in the treatment of the poison by means of Labarraque solution, a solution of chlorinated soda. In the first stage it may be used in full strength, but should be washed off at once with cold water. This is followed by an application of a weak solution of the same in the proportion of a tablespoonful of the solution to a pint of water, by means of a fold of cotton or linen fabric kept constantly applied for several hours. The application of Labarraque has never failed in the writer's hands.—*Medical Review of Reviews.*

Sahli's Desmoid Reaction in Gastric Diagnosis.—Thomas R. Boggs describes Sahli's desmoid reaction. In order to carry out this test a pill of methylene blue or iodoform, or both together, is placed in a rubber sack. This sack is made by twisting the pill in the center of a square piece of thin rubber dam. The twisted neck is tied with three turns of number oo raw catgut previously soaked until soft in cold water. The knots are made on the same side of the bag. This test causes the patient no distress, and, as it is given at the principal meal, it is subjected to the activities of the gastric functions when they are at the height of their stimulation. The desmoid pill is relatively heavy and so remains in the stomach for the maximum length of time. It thus fully tests the activity of the gastric juice. It often gives a positive result when, with the test breakfast, an absence of free hydrochloric acid is indicated. As Sahli pointed out, this is a matter of considerable diagnostic importance in distinguishing cases with true achylia, carcinoma, or pernicious anemia from less serious disorders in which the Ewald breakfast is insufficient to cause an excess of hydrochloric acid. The writer has examined thirty-four cases in which there was impairment of the gastric function, in addition to twelve normal persons. The latter were all positive. In the carcinoma cases, all but one gave a negative test. This patient was an ignorant negro in whose case the test was unsatisfactory and unfortunately could not be repeated. All of the seven cases of pernicious anemia gave negative tests. A case of secondary anemia of long duration gave a positive test. Various other interesting negative tests were observed. In each case with two exceptions the result of the test was compared with the findings of the Ewald breakfast or Fischer's meal, or both. The results of these experiments, which are given in a tabulated form, seems to bear out Sahli's contention that the desmoid pill does show the ability of the stomach under the best conditions. The writer believes that its principal value is as a test for free HCl. As he says, it cannot replace the test meal, but is a useful adjunct to this essential measure. In the stools of the negative cases the pills which were found showed no evidence of digestion, yet in most cases the intestinal digestion of foods, including meats, was good. The writer declares that this fact speaks strongly for the specificity of the test for gastric digestion.—*Bulletin of the Johns Hopkins Hospital.*

Venous Compression as a Diagnostic Method in the Case of a Latent Roseola.—René Hornad cites the case of a patient in Jaboulay's service. This patient had entered the hospital with an anal fistula. The man had had a chancre. A distinct roseola was noted on the front of the abdomen of this patient. Stasis of the blood current brought about by venous compression rendered the roseola far more evident. An elastic rubber band is a simple means for causing this compression, although a cloth bandage will be of equal service. When this is put around the arm, for example, the color soon becomes violet in hue and the spots of the eruption, which may be latent, become apparent, red, copper-colored, and livid. The writer has been able by this means, in some cases, to detect a roseola when it could not be seen even with a blue glass. Venous compression might be applied for the early diagnosis of eruptions other than specific.—*Lyon Médical.*

The Rapidity of Absorption of Odors by Milk.—F. Bordas and Toutplain have determined, in their researches which they have made with the aid of formic aldehyde, that this is absorbed most rapidly by milk which has been freshly drawn. This absorption of aldehyde by milk is so rapid that it has been suggested to use the impregnated milk for revealing traces of formic aldehyde in the air.—*La Presse Médicale.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 12, 1907.

THE LONGEVITY OF COLLEGE ATHLETES.

A VALUABLE contribution to the literature of this subject has recently been made by Dr. W. G. Anderson, the head of the Yale gymnasium. He notes the general impression that the star athletes from American colleges do not live as long as do their less athletic fellows. "A good many people claim," he says, "that the highly-developed athlete has more muscle and more lung power than he can use when he graduates and takes up his long apprenticeship in some sedentary occupation. If he is not careful the very power of lung and heart which made him a force in the long four-mile pull, if he be a crew man, becomes a danger to him, because there is no call in his every-day life for the abnormal development he acquired in college. If he does not keep up some pretty vigorous exercise outside of office hours the lung tissue developed in his college life falls into disuse and may be the indirect cause of consumption, or the heart, forced to do overwork in the strain of the competition in the big sports, and overdeveloped, may retaliate in after life by refusing to do its work in some great stress, like pneumonia, for instance."

The athletic records of Yale show that between the years 1855 and 1905 the number of men who gained positions on either the crew, baseball, football, or track teams was 807. Of this number 58 have died. Of these 58, 18 were crew men (naturally as this is the oldest sport), 16 were football men, 13 track, and 11 baseball men. If an estimate be made on the basis of the average of years in the life of the sport it is found that the greatest mortality has occurred among the football men. Crew men were second, track men third, and baseball men fourth with an extremely low average. Compared with the select mortality tables of the Actuarial Society made up from mortality averages all over the country, the athletes show a remarkable longevity.

As contrasted with these figures are those collected by Dr. Anderson as to the mortality of the general graduates, who have not won team positions, though many of them have doubtless done more or less systematic athletic work. During the fifty years above stated 10,922 men have been graduated from the academic and scientific departments. Of this number 1,406 have died; that is 12.9 per cent., as against 7.2 per cent. of the athletes. Consumption carried off 12 of the 58 deceased athletes, but this percentage is not greater than would be expected among nonathletes from a similar cause, as is proven by reference to the records of the large insurance companies. "Deaths from heart disease in the list of 58 men were 4 at the ages of thirty-five, fifty-seven, sixty-eight, and seventy. The average is very low. Pneumonia carried off 6, typhoid fever 5, and typhoid pneumonia 2. Those who wish to push their argument that high athletics are bad for the lungs and heart might find some ground for that argument in the fact that 24 of the 58 deaths were caused by lung trouble of various kinds, and heart failure. The table of deaths further shows that 9 of the 58 athletes met violent deaths, of which 2 were suicides. One died of dissipation, which was not traceable to participation in athletics."

Dr. Anderson's paper is all the more valuable because it is temperate in tone. He is not seeking to prove or disprove any particular theory, but is content to let the facts and figures speak for themselves. He declares that the "inevitable conclusion from the figures gathered is that the Yale man who came to high honors in the major sports of the last half century has more than the ordinary man's share of long life." But he freely admits that "whether this is due to his high development as an athlete or to the original strength of the man himself is still unproven, and seems likely to remain so unless some more perfect means of comparison can be found."

FETAL MALFORMATIONS.

AMONG the aspects of the obstetric art to which little attention is paid by the general practitioner is the subject of fetal deformities. This may possibly be due to the vagueness of the etiology of the subject and the comparative rarity of such malformations of the major grades, for many physicians never meet with an instance of this kind even during years of practice. The condition has provoked much discussion, but no satisfactory explanation has yet been advanced. Heredity may perhaps play some part in the production of deformities of a minor degree such as hypospadias, harelip, etc., but monstrosities in the generally accepted sense can hardly ever be of direct hereditary origin as the subjects of these rarely arrive at a stage where procreation is possible. The so-called maternal impression theory is ordinarily assumed by the laity to afford a sufficient explanation of such anomalies, and some physicians also give credence to a belief which has been repeatedly shown to be, in most cases at least, without foundation, for the shock or other disturbance experienced by the mother is usually felt at a period when the fetus has already reached a stage of perfect anatomical development when it seems impossible that further changes can take place.

In a recent article by Cooke in the *American Journal of Obstetrics* for December, 1906, the writer points out that some relation exists between the production of fetal deformities and the quantity and quality of the liquor amnii and even claims that the diagnosis of these changes has a prognostic value. He has observed that this anomaly is frequently accompanied by maldevelopment in the infant and cites seven cases of oligohydramnios or polyhydramnios in which the fetus was malformed—and in five out of the series the condition was foretold before birth. Even the type of malformation can, according to Cooke, be foretold in a general way, for while deformities of the trunk seem to occur in

cases of polyhydramnios, loss or shortening of the extremities is more usual when oligohydramnios is present.

The amniotic bands which are believed to cause the latter class of deformities are not always present, and it is more probable that the malformations are due to destructive atrophy of the parts brought about by direct pressure of the uterine wall unrelieved by the interposition of the normal amount of amniotic fluid. In connection with this theory there are still a number of points unaccounted for, but the prognostic feature of the writer's statement is interesting. So long as nothing can be done to correct the condition, however, it may be just as well for the medical attendant to guard the knowledge so acquired very closely, for it will without doubt prove unwelcome to the prospective parents and their kin, and—well, "sufficient unto the day is the evil thereof."

The Urine in Psoriasis.

The attempt to determine by analysis of the urine the faults of metabolism which are believed by many to be the ultimate cause of various eruptions, has been made so often, and with such uniform ill-success, that an investigation which promises even an explanation of the failures is most welcome. In their report on the urine of psoriatics, Brocq and Ayrignac (*Annales de Dermatologie et de Syphiligraphie*, May, 1906) lay particular stress upon two precautions which are often neglected, and the neglect of which would vitiate any experiment. In the first place, they give an exact definition of psoriasis, limiting it, for the purpose of this investigation, to cases showing characteristic clinical symptoms and excluding all those about which dispute is possible. There are so many cases of doubtful diagnosis, cases showing every possible gradation from frank psoriasis on the one hand to typical dermatitis seborrhoeica on the other, that this restriction of the investigation to an easily recognized group is the only way to avoid the chance of including cases which later study may prove to be not psoriasis at all. The same precaution should be observed in dealing with eczema and other dermatoses also. In the second place, they show that there is no one normal urine for all healthy individuals, but that each form of diet in a healthy subject has a corresponding urine, and that the variation caused by diet in a healthy subject is greater than the difference between the urine of a healthy person on a fixed diet and that of a psoriatic on the same diet. It is absolutely necessary, therefore, to know exactly what diet a patient is taking, and what kind of urine would be secreted by a healthy person living on the same diet, if we are to discover the changes caused by disease. Of course this is an old story, but if we may judge from the broad conclusions sometimes drawn from experiments in which this factor is neglected, the lesson it teaches is still needed. The importance of these precautions is, indeed, the most instructive part of the article, for the results of repeated and careful analyses were so often contradictory that the authors have been forced to conclude that the study of the different urological coefficients does not by any means establish a urinary formula characteristic of psoriasis. It seems to be unquestionable that all patients subject to psoriasis suffer from some kind of nutritive disorder, but the character of the disorder varies in different cases.

Fever of Pregnancy.

Physicians are by no means at one in regard to this peculiar affection. It has been described by various investigators, among whom are Tarnier and Ahlfeld. In general, it is classified as acute and subacute or chronic. Edgar believes these to be entirely separate conditions. He says that the acute fever of pregnancy bears a likeness to such conditions as acute miliary tuberculosis, typhoid fever, and septicemia. The chronic type, however, seems to be a neurosis with participation of the heat center. From a clinical point of view it often resembles a confirmed phthisis. Among those who are opposed to the use of this term "fever of pregnancy" is Kleinwächter. He does not believe that this condition is an indication for the termination of pregnancy. In the *Revue Médicale de la Suisse Romande*, of November 20, 1906, René Koenig reports work that has been done on this subject in Jentzer's gynecological and obstetrical clinic of Geneva. From the experience gained from the study of this affection in that clinic, the importance, in face of an abnormal rise of temperature in pregnancy, of never losing sight of the possibility of the existence of appendicitis or of pyelonephritis is emphasized. Pyelonephritis is always easy to diagnose when one thinks of it. In the presence of symptoms of peritonism when an affection of the urinary passages can be excluded surgical intervention should not be too long delayed. It is better to practise an unnecessary laparotomy than to wait for symptoms which clinch the diagnosis of generalized peritonitis. As to appendicitis occurring during pregnancy, Mundé published the first well-established case in the Medical Record of December 1, 1894. In 1898 Fraenkel reported thirteen cases and Pinard forty. In 1899 Koenig succeeded in collecting nearly one hundred. Since these reports many observations have been made on this condition. Appendicitis is a complication fairly rare in the puerperium. As to appendicitis in pregnancy the pessimistic statistics which exist hardly represent conditions as they really are, for many slight cases are never reported, and indeed many are not even noted. The diagnosis of appendicitis in pregnancy is not often easy, and in some cases it presents insurmountable difficulties. Various opinions are held concerning the treatment for this condition. Prophylaxis plays an important rôle.

The Treatment of Gonorrheal Epididymitis.

In preantiseptic times French surgeons sometimes treated cases of this affection by incision with the idea of relieving tension. The frequent occurrence of infection, suppuration, and even necrosis brought the method into discredit, however, and for years the treatment of this complication of specific urethritis has been a very conservative one. A return in principle to the methods of the French surgeons is suggested by Schindler (*Deutsche medizinische Wochenschrift*, December 20, 1906), who seeks to relieve the tension due to the swelling of the epididymis by puncture, and if possible, aspiration. The punctures are made at the point where the tenderness is greatest, and if no secretion can be aspirated, are repeated several times in different directions. Strange to say, the author has not found that the procedure is at all painful, and he directs that it should be carried out without any attempt at local anesthesia, as the latter serves only to increase the discomfort of the patient. The effect of the puncture is seen in the prompt relief of pain, in the subsidence of the fever, and in the rapid

resolution of the induration. The author made use of this method in twenty-three cases of gonorrheal epididymitis, performing forty-four punctures on these patients, and found that, as compared with the conservative method of treatment by rest in bed and local applications, the duration of the detention from work was reduced by about one-half. He also tested in a series of cases a form of Bier's treatment by hyperemia, but although the results obtained were encouraging he does not consider that the method is as satisfactory as the treatment by puncture. He has not yet tried the combination of the two, though it is not impossible that by this means still better results might be obtained, for, unfortunately, even the punctures do not cause complete absorption of the exudate and restoration of the epididymis to its normal condition to take place. Even though this suggestion of Schindler's should prove as successful in other hands as in his own, the most important consideration in connection with gonorrheal epididymitis will still consist in prophylaxis, first on the part of the physician, who by judicious treatment must prevent the infection from penetrating to the posterior urethra, and second on the part of the patient, who must be educated to seek proper medical advice at the earliest indication of infection, and thus render the task of the physician less difficult. The second requirement is, however, one which the circumstances in the case unfortunately render very difficult of fulfilment.

Exploratory Puncture of the Brain.

The exploring needle has long been regarded as one of the most useful aids to the diagnostician and there are now but few recesses of the body that have not been subjected to this mode of inquiry. Kocher, some years ago, suggested exploratory puncture of the brain through fine drill holes made in the calvarium, and subsequently the method was developed and a careful technique described by Neisser and Pollack. These authors perforated the skull by means of drills of small diameter operated by an electric motor. Although they reported favorable results in a considerable number of cases, the method has not seemed to find ready acceptance, and it is therefore interesting to note that it has gained another supporter in Ascoli (*Berliner klinische Wochenschrift,* December 17, 1906), who gives the histories of six cases in which more or less important diagnostic information was obtained by this means. The method followed was in most particulars that of Neisser and Pollack, though the drills were actuated simply by means of an ordinary dental engine. Ascoli speaks of the technique as not being especially difficult, and states that the procedure can be carried out under cocaine anesthesia without causing undue discomfort. In none of his cases does it appear that any undesirable results followed the twelve punctures made, though, of course, this is by no means a guarantee of the harmlessness of the procedure, and numerous unpleasant possibilities at once suggest themselves. Still it must be borne in mind that patients for whom such a method would come in question are likely to be already in a precarious state, and exploratory puncture is probably a less serious procedure than the exploratory trephining that is oftentimes recommended. Brain surgery has progressed so greatly of recent years that a method which, like the one advocated by Ascoli in the article referred to, has some prospect of utility deserves at least to be tested and have its actual value definitely determined.

Mimicry of Malignant Disease of the Bowel.

Disappearance of tumors supposed to be malignant is common enough, and sometimes operation discloses a very different state of affairs from that assumed to exist. At a recent meeting of the London Clinical Society (*British Medical Journal,* December 22) Mr. Moynihan reported six cases in which he had operated within the last few years in which a diagnosis of malignant disease of the intestine had been made at the time of operation or before, yet subsequent examination of the specimens or the after-history of the patients showed the incorrectness of the diagnosis. For instance, a woman of twenty-nine years had intestinal obstruction due to a growth blocking the rectum. Left inguinal colotomy was performed, and six weeks later the whole of the rectum and sigmoid flexure below the colotomy opening were removed by the abdominoperineal route. Examination of the specimen, which was shown, revealed no evidence of malignant disease. The rectal walls were thickened and stenosed. The mucous surface showed heaped-up, irregular masses of soft growth, here and there ulcerated to a degree which resulted in festoons of mucous membrane being left, attached at each end, free in the middle. There was no evidence of tubercle or syphilis. The other histories are similar. Mr. Moynihan observed that mimicry of malignant disease in the cecum and ascending colon by a hyperplastic process was well known. Inflammatory tumors presenting all the clinical appearances of cancer may exist in all parts of the large intestine. Some of these may be due to the presence of false diverticula. Such cases are analogous to those tumors of the stomach which disappear after gastroenterostomy.

The Effect of the Tropical Sun on Pathogenic Bacteria.

The well-known resistance to infection exhibited by the natives of tropical Africa has led to the conclusion that the natural protective powers of these individuals are developed to an unusual degree. According to the reports of surgeons who have practised in these regions injuries of all sorts, even when brought under observation with the most unaseptic sort of first-aid dressings, heal without suppurative complications, and primary union is often obtained in the most unpromising wounds. It is rather unlikely, however, that the benign course observed in such cases is altogether to be put to the credit of the black man's fortunate idiosyncrasy and it is probable that to some extent at least the prevailing paucity of pathogenic bacteria may have something to do with the absence of the proneness to infection that exists in civilized regions. An interesting communication by Martin (*Münchener medizinische Wochenschrift,* December 18, 1906), bears witness to this opinion, for his experiments appear to indicate that the climatic conditions in the tropics are more actively hostile to bacterial life than is usually supposed. This observer occupies an official position in a German colony in tropical Africa, where the average temperature during the eight warm months is 77° F. at six in the morning, 144° in the noonday sun, and 77° again at night. These extreme fluctuations in temperature were considered by the author as likely to be particularly unfavorable to bacterial life, and he tested the matter by exposing in various ways pure and mixed cultures of various pathogenic organisms to the influence of the sun and air. He also tested the bacterial contents of the air both indoors and out, and of the soil. All

of these experiments lead him to the conclusion that in tropical regions there is a well-marked scarcity of pathogenic bacteria. This is probably in great measure due to the sun's heat, though undoubtedly considerable importance also attaches to the bactericidal effect of the light rays. It was found that a number of nonpathogenic organisms were not susceptible to these influences, however. A series of tests of sand taken from the shore leads to the interesting conclusion that the mechanical action of the surf appears to render sterile the sand on beaches exposed to the action of the waves.

Neuronophagia.

During recent years the study of the nervous system has absorbed the attention of various brilliant investigators. Many problems are yet in the realms of obscurity, and any new and careful work is welcomed, not only by the neurologist, but also by the general practitioner. The recent reports by Laignel-Lavastine and Roger Voisin of the laboratory investigations which have been carried on in connection with the Laënnec Medical Clinic (L. Landouzy), and that of Jules Voisin at the Salpêtrière are of the greatest interest. It is known, as these workers state, that when the central nervous system in animals killed in full health is examined there are seen among the various nerve cells only certain slightly colored nuclei which correspond to neuroglia without any tendency to agglomeration, either perivascular or pericellular. On the contrary, when one examines the central nervous system of an animal which has succumbed to any affection whatsoever, the following condition can be seen: all about the nerve cell there are small rounded nuclei, variable in appearance and in color, some of which are in relation with the protoplasm of the cell, and some of which even encroach upon the nerve tissue. Here the cellular protoplasm has disappeared. This disappearance resembles the figures of phagocytosis. Many authorities have supposed that the pericellular nuclei attack and digest the cell, and Marinesco has named these small, round elements neurophages or neuronophages, and the phenomenon itself neuronophagia. The writers conclude that these forms spoken of do exist. The neuronophages are never united in all parts in the cellular protoplasm. They are diverse in nature (neuroglia nuclei, lympocytes, polynuclears, connective tissue cells, endothelial cells, plasma cells), and in origin (ectodermic and mesodermic). From their appearance one cannot always infer their nature; it is necessary to make a complete examination of the anatomo-pathological concomitants. Their rôle depends upon their origin. The elements of ectodermic origin play the rôle alone of substitution. Among the elements of mesodermic origin Laignel-Lavastine and Voisin have not determined any neuronophage, properly speaking, in the sense of Metchnikoff; but the lympocytes, if they are not cytophages, may produce cytolysis. It is then in this cytolitic rôle alone that these cells called neuronophages are found. Neuronophagia, therefore, considered as a special case of phagocytosis, properly speaking does not exist.

A New Theory of the Pathogenesis of Hyperemesis Gravidarum.

The numerous theories which have been advanced to account for the production of this condition may with advantage be classed in three groups, depending on whether the cause resides in the uterine contents or in secondary changes in the maternal generative apparatus or other organs of the mother. The theories of the first group may again be divided into two classes, according to whether the etiological factor is assumed to reside in the fetus itself or in the fetal adnexa. The theories of the second group are based on changes in the uterus or its appendages. Those of the third are distinguished by the fact that the nervous system, the urinary apparatus, or the digestive tract is regarded as the source of the difficulty. Stella, who has recently studied this subject (*Gazzetta degli Ospedali*, No. 126, 1906), considers that the symptoms of the hyperemesis of pregnancy can be directly attributed to the fact that during this time there is a restriction in the internal secretion produced by the ovaries. If such were the case it is possible that the abnormality might be corrected by the administration of ovarian extract. The writer resorted to this in a number of cases, which although insufficient in number to warrant drawing definite conclusions, demonstrate so far as they go the possibility of truth in the theory. In no case at any rate was the effect of these preparations entirely negative. In submitting the proposition to further trial, it is also suggested that the ovarian extract be given with a prophylactic intent in cases in which certain gastrointestinal disturbances indicate the possibility of further trouble. As the treatment is entirely harmless, Stella holds that it should be tried in every instance before abortion is resorted to.

Pneumonia Paralyses.

The paralytic affections which have been observed in adults during the course of a pneumonia or in convalescence are subject to considerable variation in their clinical manifestations. This, according to Daireaux, depends on the age of the patient. Those of very advanced years are subject to hemiplegias which always end fatally. In younger individuals, although the symptoms may be very severe, they are more apt to be recovered from. Daireaux had occasion to observe a case in which the hemiplegia following pneumonia was of this transitory type, and a few other instances have been reported in the literature. The general paralyses are characterized by a polyneuritis or, in exceptional cases, as in one reported in the *Archives générales de Médecine*, No. 36, 1906, by poliomyelitis. The damage to the nervous system in these cases can most likely be accounted for by the direct action of the toxins of the disease on the nervous system. Observations of this character are in thorough accord with the modern idea that pneumonia is a general, rather than a local disease, in which, as in most infectious diseases, the peripheral nerves as well as the spinal cells may be damaged. The comparatively short-lived character of the pneumococcus, as well as the short period during which the toxins are being developed, may serve to account for the transitory character of the paralyses in younger patients. Those which occur in more advanced years, however, during or after a pneumonia, must be attributed to disease of the cerebral vessels, which constitutes a complication rather than the result of an infection.

The New York Neurological Society.—At the annual meeting of this society, held on January 8, 1907, the following officers were elected: *President*, Dr. Charles L. Dana; *Vice-Presidents*, Drs. B. Sachs and L. Pierce Clark; *Corresponding Secretary*, Dr. Hallock; *Recording Secretary*, Dr. E. G. Zabriskie; *Treasurer*, Dr. Graeme M. Hammond.

News of the Week.

Lectures on Insanity.—The Psychiatrical Society of New York has arranged for a series of four lectures on the problems of insanity, to be held under the auspices of the Academy of Medicine, on Saturdays, January 19, February 2, February 16, and March 2, 1907, at 8:30 P. M. The purpose of these lectures is to put within the reach of the medical profession and also of the non-professional leaders of sociological interests a program of work and facts for orientation, with a view to the organization of a movement toward prophylaxis and the development of sound interest in this eminently important topic. The first lecture will be given by Dr. Adolf Meyer, on modern psychiatry, its possibilities and opportunities; the second lecture, by Dr. August Hoch, on the manageable causes of insanity, exclusive of heredity; the third lecture by Dr. C. L. Dana, on the data of heredity and their application in psychiatry; and the fourth lecture by Dr. Allen McLane Hamilton, on the development of the legal regulations concerning the insane. Physicians and others interested in a movement toward prophylaxis and the best management of mental disorders are cordially invited.

Typhoid Fever in Scranton.—Improvement is reported in the typhoid situation at Scranton as the number of new cases is diminishing, although it is admitted that the entire water supply is contaminated and the disease is also appearing in the surrounding localities. The number of cases so far reported is over one thousand, and over fifty deaths have occurred. In Pittsburg also the water supply is infected, and the situation is serious owing to the overcrowding of the hospitals.

In Memoriam of Dr. Mary Putnam Jacobi.—At the memorial meeting in honor of the late Dr. Mary Putnam Jacobi held on January 4 at the Academy of Medicine, the Women's Medical Association agreed to raise a fund of $25,000 to establish the Mary Putnam Jacobi Fellowship, the income from which is to be used to defray the expenses of some woman medical student in whatever country she chooses to study. It was announced that about $2,000 had already been pledged. Eulogies were pronounced by Dr. William Osler, Richard Watson Gilder, Dr. Elizabeth M. Cushier, Mrs. Florence Kelley, Felix Adler, and Dr. Charles L. Dana.

New Training School for Bellevue.—Plans have been filed for the new six-story fireproof training school for women nurses for Bellevue and Allied Hospitals, to be erected at a cost of $575,000, in Twenty-sixth street, east of First avenue. It is to have a frontage of one hundred and fifty-one feet and a depth of one hundred and ninety-four and one-half feet. The main floor will contain the assembly hall and a dining hall, and the second floor will have a laboratory. The other floors will be fitted with sleeping chambers, and there will be a roof garden with a pergola ornamented with terra cotta columns. The building is to cost $575,000.

Antivivisection Petition.—A monster petition was presented last month to the British House of Commons in behalf of the National Canine Defence League. It was announced that this document consisted of nine miles of parchment, weighing a quarter of a ton, and was subscribed to by 400,000 signatories. The petitioners set forth that they were opposed to the vivisection of dogs, and prayed the House to pass a Dogs' Protection Bill, which should prevent those animals from being made the subject of experiment.

Changes Recommended for the Cook County (Ill.) Hospital.—In his inaugural message, Edward J. Brundage, President of the Board of Commissioners of Cook County, recommends among other things that in every abnormal case admitted to the Cook County Hospital, Chicago, the patient should receive the attention of an expert pathologist, and in order that the service may be brought up to the required standard of efficiency, he advocates reorganizing the present pathological department. He believes an effective reorganization may be accomplished by employing an expert pathologist, requiring him to live in the hospital and give it all his time, and providing the department with the best modern equipment. In further development of the scientific side of the service at the hospital, he recommends that a permanent *x*-ray department be created.

American National Red Cross.—The annual report of the National Red Cross shows that during the year the organization collected $3,358,974 used for relief given to the sufferers from the Vesuvius eruption, the San Francisco disaster, the Japanese famine, the earthquake in Chili, and the Mobile storm. The report shows that there are branch organizations in twenty-nine States, with a total reported membership of about 18,000. Before the end of the present year it is expected that branches will be organized in all States and Territories, including Hawaii and Porto Rico.

The Cartwright Prize of the Association of the Alumni of the College of Physicians and Surgeons of Columbia University is to be awarded at the coming commencement. Its value is $500, and it is given for the best essay containing the results of original work in medical research. Information regarding the conditions of the competition may be obtained from Dr. H. E. Hale, 752 West End avenue, New York, who is the secretary of the association.

Deaths from Snake Bite in India.—The number of persons killed in India in 1905 by wild beasts was 2,054, as against 2,157 in the previous year. The number of deaths reported from snake bite, 21,797, is also a little smaller than that of 1904.

Ambulance Service Stopped.—Owing to alleged delay in answering ambulance calls the Board of Police Surgeons last week discontinued the ambulance service of the Washington Heights Hospital. Until the matter has been settled the district from West Eighty-sixth street to Spuyten Duyvil Creek will be assigned to the J. Hood Wright Hospital.

The City's Vital Statistics.—The number of births in the city of Greater New York last year was 111,772, an increase of 8,000 over 1905. The number of marriages was 48,355, an increase of 5,700. The deaths reported had increased by 2,492, the total being 76,206. There was an increase of deaths from diphtheria, cancer, heart disease, nephritis, old age, suicide, homicide, and violent deaths due to accidents, while there was a decrease in deaths from typhoid fever, malaria, whooping cough, cerebrospinal meningitis, influenza, bronchitis, and gastrointestinal disorders in children under five years of age.

Statistics of the Coroners' Office.—During the past year there were 5,890 deaths reported to the Coroners' office during the year, and of this number there were 3,160 deaths of a violent character. The total number of deaths in which the injuries received were chargeable to some other person was 549. The total number of cases tried by the Board

of Coroners and presented to juries during the year was 936; the number of inquests held at which testimony of witnesses was taken and reduced to writing and verdict rendered in accordance therewith was 1,224; the total number of inquests held where a verdict was rendered upon the sworn testimony of the Coroners' physicians, was 3,730; the total number of autopsies performed by the four physicians attached to the office was 1,112. There were 68 deaths due to caisson disease and accidents in connection with the tunnel work going on under various parts of the city and the North and East rivers.

Immigration Statistics.—The records of the Immigration Department issued last week show that in the past twelve months there has been an increase of nearly 400,000 in the number of persons landing at this port over the preceding year. There were 119,231 first, 134,380 second, and 944,017 third class passengers reaching this port, making a total of 1,198,434 that entered the country in 1906. Of this number 142,603 were citizens of the United States, and 1,055,831 were aliens.

Tobacco Smoking in Austria.—Recently published statistics furnished by the Austrian Government tobacco monopoly indicate an enormous increase in cigarette smoking in that country. Nearly four billion cigarettes were smoked in Austria in 1906, as well as some 1,200,000,000 cigars. Thirty years ago 2.3 cigarettes was the annual average consumption per capita for the whole population. Last year the average was 145.5 per capita. In the same period the consumption of cigars decreased from 49.7 to 44.3 per capita. Last year 31,000,000 fewer cigars were smoked than in 1904, while cigarettes showed an increase of 167,000,000. During the year the amount spent for smoking tobacco was $50,000,000, which was $200,000 more than in 1905. The receipts of the tobacco monopoly exceeded the expenses by more than $30,000,000.

A New Hospital on the East Side.—What is to be known as the Mount Merijah Hospital is to be founded in the lower east side by the Federation of Galician and Bucovinean Jews in America. Two four-story dwelling houses at 138 and 140 East Second street have been secured and will be altered for hospital and dispensary purposes. About thirty beds are to be maintained, and the hospital will be free to persons of all races and creeds.

Midwife Convicted as a Nuisance.—The District Attorney's office has found it so difficult to secure convictions of abortionists on the charge of performing illegal operations that in future the experiment will be made of trying such offenders under the charge of being common nuisances. A midwife was convicted last week under the provisions of the code pertaining to common nuisances and sentenced to a year's imprisonment in the penitentiary and $500 fine. One witness who had been employed in the house of the prisoner testified that in three months over fifty women had been operated on in the house, and one had died.

Rabies.—Seven persons have been bitten recently by rabid dogs in the neighborhood of City Island, where there are at present a number of dogs at large that are supposed to have been infected. The Health Department and the Society for the Prevention of Cruelty to Animals are making efforts to trace these animals and imprison them. A somewhat similar state of affairs is also in existence in the neighborhood of Mount Vernon and Port Chester, where several people have been attacked by rabid dogs. Three persons are under treatment who are believed to have been infected by a mad cow.

American Physiotherapeutic Association.—An invitation is extended to physicians interested in the study and legitimate practice of the physical (drugless) therapeutic methods, notably electrotherapy, phototherapy, mechanotherapy, hydrotherapy, suggestion, and dietetics, to join the American Physiotherapeutic Association. The officers of the association are: *President*, Dr. H. H. Roberts, Lexington, Ky.; *Secretary*, Dr. Otto Juettner, 8 West Ninth street, Cincinnati, Ohio; *Treasurer*, Dr. George H. Grant, Richmond, Ind.; *Executive Council*, Drs. W. F. Klein, Lebanon, Pa.; James Hanks, Brashear, Mo.; J. W. Unger, West Point, Miss.; Charles S. Northen, Talladega, Ala.; R. W. Gibbes, Columbia, S. C.; S. J. Crumbine, Topeka, Kan., and A. L. Blesh, Guthrie, Okla.

Congress on Climatotherapy and Urban Hygiene.—The third congress on these subjects will be held on the French Riviera from April 1 to 10, 1907. The sessions will be held at Cannes, Monaco, Mentone, and Ajaccio; but all the towns and stations on the Mediterranean Littoral are included in the program—Cannes, Nice, Monte Carlo, Mentone, Hyères, Antibes, Grasse, St. Raphaël, Juan les Pins, Beaulieu, Cap Martin, Thorenc, etc. The congress will last about one week on the French coast, and will finish in Corsica. The general secretary is Dr. Verdalle, 1 Boulevard d'Alsace, Cannes. The congress will be held under the presidency of Dr. Calmette, director of the Pasteur Institute, Lille.

Perry County (Miss.) Medical Society.—This society has elected the following officers for the ensuing year: *President*, Dr. I. H. C. Cook; *Vice-President*, Dr. W. R. Thomas; *Secretary and Treasurer*, Dr. S. Lewis Knight.

The Riley and Pottawatomie (Kan.) County Medical Society.—The following officers have been elected for this organization: *President*, Dr. T. R. Cave, Manhattan; *Vice-President*, Dr. George H. Letsinger, Riley; *Secretary*, Dr. J. C. Montgomery, Manhattan; *Treasurer*, Dr. C. A. Roberts, Randolph.

Dr. W. W. Keen has resigned from the chair of the principles of surgery in Jefferson Medical College and has been elected emeritus professor. He will spend the coming year in Europe.

Police Surgeons Appointed.—Dr. Henry G. Webster and Dr. Thomas A. McGoldrick of Brooklyn last week received appointments as police surgeons.

Dr. Henry Leffmann has resigned from the Philadelphia Board of Health for the assigned reason that there is nothing of an administrative character for that body to do. The remaining members are Dr. A. C. Abbott and Dr. Leonard Pearson.

The American Hospital for Diseases of the Stomach was formally opened at Philadelphia on January 3. Dr. Lewis Brinton is chief physician, Dr. John B. Deaver chief surgeon, and Dr. John B. Shober gynecologist. Dr. Ludwig Loeb is associate surgeon, Dr. L. Napoleon Boston director of the research laboratory, Dr. J. R. Strawbridge assistant physician, Dr. Francis B. Jacobs pediatrist, Dr. James C. Wilson consulting physician, and Dr. James Thorington consulting ophthalmologist.

Sanatorium for Insane Hospital.—The Illinois Western Hospital for the Insane at Watertown, Ill., contemplates erection of a modern sanatorium at a cost of $100,000. This is an improvement or addi-

tion which the superintendent and trustees will ask of the new Legislature.

Obituary Notes.—Dr. Edward Oliver Belt of Washington, D. C., was one of the victims of the wreck on the Baltimore and Ohio Railroad at Terra Cotta on December 29. Dr. Belt was graduated from the Maryland School of Medicine in Baltimore in 1886 and was well known as a specialist in diseases of the eye.

Dr. Richard M. Coghan of Providence, R. I., died on January 3 at the age of twenty-eight years of scarlet fever contracted from a patient. Dr. Coghan was graduated from Brown University in 1901, and received his medical degree from the Jefferson Medical College in 1905.

Dr. Joseph A. Aldrich, who was formerly a surgeon in the United States Army, died in this city on January 4 at the age of eighty-nine years. He was stationed at New Ulm, Minn., during the Indian wars and distinguished himself for bravery at that time.

Dr. Joseph W. Glynn of Flatbush died on December 30 in his thirty-seventh year. He was graduated in 1894 from the Long Island College Hospital.

Dr. Olive F. McCune of Brooklyn died on January 4 in Binghamton, N. Y., at the age of seventy-eight years. She was born in Delhi, N. Y., and had practised in Brooklyn for about thirty-five years. Her husband, who was also a physician, died some years ago.

Dr. Henry W. Dudley of Abington, Mass., died on December 29 of heart disease at the age of seventy-five years. His death was very sudden and he had been making calls up to noon of the day on which he died. Dr. Dudley was born in Gilmanton, N. H., and was graduated from Harvard Medical School in 1864. He was president of the Plymouth District Medical Society in 1878 and had held numerous other official and teaching positions. For sixteen years he had been medical examiner of the second Plymouth district, and he had practised in Abington for over forty years.

Dr. Charles Culpepper of Portsmouth, Va., died suddenly on December 28, at the age of forty-three years, after several years of broken health. He received his medical education in the University of Virginia and had practised in Portsmouth for many years.

Dr. S. Cyrus K. Bartlett of Minneapolis, Minn., died on December 27 at the age of seventy-seven years. Dr. Bartlett was born in Boxford, Mass., and after receiving his medical education at Harvard Medical School he practised in Boston for six years. In 1868 he was appointed superintendent of the insane asylum at St. Peter, Minn., and after twenty-five years of service resigned and went to Minneapolis. For the past twelve years he had been the professor of mental diseases at Hamline University.

Dr. Jacob G. Wolf of Morristown, Ind., died on December 27 at the age of eighty-three years. In 1849 he was graduated from the Ohio Medical College, and two years later he settled in Morristown.

Dr. Jeannette C. Welch of Grand Rapids, Mich., died of pneumonia on December 31. She was born in Canaan, N. H., in 1867, and was a graduate of Wellesley College and the College of Physicians and Surgeons of Chicago. She also held the degree of Doctor of Philosophy from the University of Chicago.

Dr. J. W. Standley of Alexis, Ill., died suddenly on December 23. He was born in Putnam County, Indiana, in 1848. He was graduated from Rush Medical College with the class of 1872, and practised in Greencastle, Mo., until 1880, when he went to Alexis.

Dr. William H. Dingee died at Philadelphia on December 30 at the age of thirty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1896. He was connected with the eye, ear, and throat dispensaries of the Samaritan, Episcopal, and St. Mary's Hospitals.

Correspondence.

TREATMENT OF ACUTE SEPTIC PERFORATIVE PERITONITIS.

To the Editor of the Medical Record:

Sir:—The letter of J. J. Brownson, M.D., in your issue of December 15, 1906, anent the subject of treatment of acute septic perforative peritonitis, contains statements that should not be allowed to pass unchallenged, for the wide publicity given them by your journal might result in the acceptance here and there of misjudged conclusions and consequent deprivation to many of the chances of possible assistance through operative interference.

The conclusions expressed by Dr. Brownson regarding hopelessness and contraindication of operation in cases of general peritonitis are those that were generally accepted some six or eight years ago, but surgeons who have been awake these few years have noted quite some progress, and think differently, and have proven differently to-day. The assertion of Drs. Marshall and Quick is up-to-date: "We operate in every case when the radial pulse can be felt. Early, intermediary, and late operations, as defined by hours, days, are terms that should be relegated to the attic, etc. We have awakened from that condition which makes a god of pulse and temperature." The definiteness of this statement is only accentuated by Dr. Brownson's criticism, "Or, in other words, they care nothing for the condition of the patient or the period of the disease. All they want is the diagnosis and a pulse at the wrist when they cut away." This is exactly the case, especially in regard to peritonitis, for, according to Dr. Brownson's own statement, these cases are hopeless, "forlorn tasks with which a surgeon should not risk his reputation," if not operated on. Then what is to be lost by operation? The surgeon's reputation? Dr. Brownson certainly does not mean to balance that against a chance of saving the patient's life. Yet the fact is that to-day a fair proportion of these patients are saved by operating on them.

It is unfortunate that we have not a better classification of "general peritonitis" than has been and is yet in vogue. The doctor is justified in referring to "what is meant by certain writers when they report cases of 'general suppurative peritonitis' terminating in recovery." But the doctor's description of the cases he refers to is not at all any more definite, in fact, less so. He says "produced by the bursting of an abscess pouring its septic contents directly into the abdominal cavity," and that no such case "will be found with a temperature of 102° and a pulse of 120. Rather will they have a temperature of 105° or 106° and a pulse of 140 or 160." The bursting of an abscess, pouring its septic contents into the abdominal cavity is the cause of the spreading peritonitis in almost all cases of diffuse septic peritonitis, both those where the infection is limited more or less to the region of the original lesion, and those of general peritonitis, which result from the further spread of the local diffuse infection, taking a longer or shorter period to develop, according to the character of the infection, the personal resistance of the patient, etc.

Perforation and peritoneal infection with a temperature of 105° or 106° and pulse of 140 or 160 is a rare combination, and does not represent the conditions in the really bad cases. These have the bad pulse, but a moderate temperature. The high temperature shows effort on the part of the system to overcome the invasion of the infection, and in so far is a favorable symptom. The bad pulse indicates want of resistance or exhaustion, and is generally accompanied by a moderating temperature as the power of resistance wanes. The outlook with a poor pulse and high temperature is better than with a poor pulse and low temperature, which are the results of want of active resistance on the part of the economy, or of the cumulative and increasing toxic effects of the infection which has been developing and spreading for some days. Here the prognosis is poor but not hopeless. This is the class of cases described by Dr. Baldwin as those he does not expect to

save, and, although they do not answer the description of the cases referred to by Dr. Brownson, are quoted by him in support of his contention. Dr. Baldwin bases his opinion on failure in two such cases, hardly sufficient to judge by, especially when others report recoveries, some more, some less, in larger series of cases.

Dr. Brownson's conclusions regarding time of operation in appendicitis cases in general, referred to briefly in this letter, are expressed more in detail in his article in the MEDICAL RECORD of October 6, 1906. He designates three periods when operation should be done, and an "intermediary period when there is fever and distention of the abdomen" when it ought not to be done. This period as the doctor defines it is very indefinite, but it evidently refers to some time between the beginning of the attack and the development of abscess. Postponement of operation till after this period can only contribute towards increasing the proportion of cases complicated with general peritonitis. When no abscess develops there is no intermediary period, and no operation until the interval. Waiting for this interval, though, would permit of the possibility of something happening as the result of an unrecognized abscess, such, for instance, as might form in the appendix or around it, and fortunately discharge into the cecum without even having been recognized, and yet end in recovery. Where is the "intermediary period" when, with no abscess formation, a concretion ulcerates through the appendix wall and permits discharge of intestinal contents into the peritoneum? Where is it when a distended gangrenous appendix suddenly bursts and discharges its bacteria-laden, not necessarily purulent, contents into the peritoneum? Where is it when infection of the general peritoneum is found coincident with almost the first signs of appendicitis? In a good proportion of cases, before the belly is opened, it is impossible to say in which any of these conditions is present or absent, or will or will not occur. Waiting for the "intermediary period" to pass before operating gives the opportunity for any accident to happen, and permits the development of the usual proportion, in unoperated cases, of a spreading peritonitis, which if said "period" is permitted to last long enough, becomes general septic peritonitis "with a temperature of 105° or 106° and pulse of 140 or 160." On the other hand, to operate when the diagnosis is made is to forestall the possibility of these accidents, and to operate in the "intermediary period" is no worse than at any other time; in fact, preferable to waiting till abscess has formed, with its concomitant inflammatory infiltration and extensive and brittle adhesions.

Nothing is as conclusive in an argument as facts, and I can cite a few such that will go to prove what I claim. Referring to my report of 147 appendectomies (MEDICAL RECORD, March 24, 1906), it is noted there that of 142 of these, 23 were operated on within two days of the beginning of the attack, 50 in three to four days, 41 in five to seven days, 18 within two weeks, and 10 in one to three months. In referring to my notes I find that among the 50 who were operated upon on the third and fourth days of the attack, presumably the "intermediary period," there were two deaths, one primarily of general peritonitis, to which the intermediary period would not apply, and in the other there was a large pelvic abscess with a gangrenous appendix, and the case was very septic. Neither of these patients could have been in the intermediary period. In fact, the causes of all the deaths in the series, as given under "mortality" at the end of the article, could, by their very nature, have no relation to the "period" in which the operation was done. In a subsequent series of over 50 appendectomies, where the time of operation was "as soon as possible" after coming under observation, there were two deaths, one in a case of a general peritonitis; the other patient was sick for a couple of weeks with a large retrocecal abscess and gangrenous appendix, in addition to an old and advanced pulmonary tuberculosis, and died of post-operative hypostatic pneumonia. As in the previous series, neither of these deaths could be attributed to operation in the "intermediary period," and as there are none in these 200 cases that could by any stretch of the imagination be ascribed to this cause, the intermediary period or any other period becomes a negligible quantity.

As to recovery from general peritonitis, and relative temperature and pulse ranges and their significance in this condition, I would again refer to the same article and, in addition, copy the following from my notes on these cases, the observations given being those of the patient's condition on admission to the hospital. Among the recoveries from general peritonitis, those with the highest temperatures were the following: temp. 105 2-10°, pulse 112; temp. 104½°, pulse 112; temp. 104°, pulse 140; temp. 103 6-10°, pulse 124. Among the deaths the highest temperature was 102 6-10°, pulse 100; others were temp. 102°, pulse 142; temp. 102°, pulse 130; temp. 101°, pulse 130; and the lowest temperature was 96½°, with pulse of 130. Among the fifty odd additional appendectomies mentioned above were fourteen cases of diffuse and general peritonitis. Their temperature and pulse ranges were within the limits given in the previous series, and on the average they were of the same nature. The results were better, due, I believe, to added experience in method of handling, especially in the mode of drainage and limitation of unnecessary manipulations, though different from Dr. Murphy's cases, in that the appendix was invariably removed. Of the fourteen there were thirteen recoveries. I shall have more to say on this subject in an article to appear in the near future.

A. E. ISAACS, M.D.

TRYPSIN FOR THE CURE OF CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD of December 8, 1906, there appeared an article under this title by William J. Morton, M.D., which article has been very extensively quoted in the lay press and has called forth considerable discussion. Into this discussion medical men have entered, contending that such articles should not be copied or published in the lay press. The lay press has answered that it was simply printing "facts," and publicity in the use of "facts" in the cure of disease was a public benefaction. Now, I do not wish to discuss the use of trypsin in the treatment of cancer, which I am using along with many other medical men, but I wish to say something about "facts" in so far as Dr. Morton's article referred to me and case No. 1 came under my observation.

Dr. Morton says that case 1 was "referred by Dr. Edw. W. Peet." I beg to correct this statement, for I did not refer the case to him and did all I could to keep the case from him. I was the family physician of the patient and she got her early knowledge of Dr. Morton through the reports of him in his connection with the treatment of the late President Harper of Chicago University. After repeatedly calling my attention to these notices the patient went to Dr. Morton and brought back such accounts of results in the use of *x*-ray that I was constrained to see him also. I did so and the results he reported did not tally with the results I had obtained with *x*-ray. I continued to attend the patient at her home and made very careful and frequent notes of the progress of the case while she was under treatment. My notes do not at all agree with the report made by Dr. Morton in his article. He says: "The patient received 32 *x*-ray treatments, extending over a period of seven weeks. The gland had reduced one-third in size, the tumor was freer, and absolutely every sign of lmyphatic infection had disappeared." The tumor did increase and decrease in size depending on whether her menses were present or remote. At all times during these seven weeks I was able to make out enlarged axillary glands and detect lymphatic infection by palpation. How any one could make such an optimistic statement about this case is beyond my comprehension. According to my observation the tumor and axillary involvement slowly but continuously progressed. And this coincides with the histories of most of my cases treated with *x*-ray. I did the first operation referred to by Dr. Morton and assisted at the second, and feel it a duty to put on record my observations of the "facts" in this case.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE RECESS—HOSPITAL SUNDAY FUND—KOCH ON SLEEPING SICKNESS—HEPATIC INADEQUACY AND GOUT—MIMICRY OF MALIGNANT DISEASE—RUPTURE OF THE DIAPHRAGM.

LONDON, December 21, 1906.

THE Xmas recess has arrived and is a welcome rest to those who have been working strenuously in the schools, whether as teachers or students. Many assiduous attendants at the societies are also pleased for the interruption of the work. I may add that the scheme of amalgamation is making haste slowly.

Yesterday, the constituents of the Hospital Sunday Fund held their annual meeting at the Mansion House, the Lord Mayor presiding. The total collections for the year amounted to £63,000. The sums collected in the places of worship reached £44,647 less than the previous year by £4,307.

The Bishop of London, in moving the adoption of the

report, thought the fund might rise to £[illegible],000, and the Chief Bailiff, who seconded, thought some of the falling off was due to week-ends out of town, and he hoped those absent from the Hospital Sunday would forward their donations. The report was adopted and Hospital Sunday for 1907 fixed for June 9.

Koch's report on sleeping sickness has been presented to the German government, and telegraphic summaries appear in our newspapers this morning. No doubt you will get the same by cable, so I will only allude to one or two points. He says the disease is not indigenous in German South Africa, and that the cases occurring there come from British territory—a statement that requires corroboration, seeing that the Glossina, as he admits, is prevalent in the German colony. He pronounces atoxyl to be a specific. He speaks of 900 cases, all serious, under treatment, and expresses the opinion that the majority of them will be cured in from two to three months. It will be necessary to watch for relapses before absolute certainty is obtained. One remembers tuberculin, and can await the verdict of the medical societies, where no doubt criticism will be forthcoming.

There was an interesting discussion at the Medical Society on the 10th inst., introduced by Sir L. Brunton in a paper on hepatic inadequacy in reference to gout and other diseases. He said people might be healthy whose muscles were unequal to heavy work, as others whose brains did not fit them for some positions. So lungs, stomachs, kidneys, etc., might be inadequate. The liver, he said, might be inadequate as regards carbohydrates, hence glycosuria; but its deficient power with regard to proteins and purins was not so fully recognized unless what passes as torpid liver be so considered. He referred to the experiments of Stokvis, which suggested that the liver is concerned in the conversion of uric acid into urea. This work he had confirmed in conjunction with Dr. Bokenham, as also continental physiologists had done. He thought probably an enzyme capable of decomposing uric acid was present in the cellular juice of the liver during active digestion, and not at other times. This enzyme might be set free by some secretion. Hepatic inadequacy as to carbohydrates needs a meat dietary, but as to purins a purin-free diet. To put every one on a purin-free diet was as absurd as to put healthy people on a diabetic's diet. The best diet for man was, as Professor Chittenden said, "a mixed diet, and not too much of it." The paper, then, was a new appearance of the old idea of torpid liver.

Sir D. Duckworth said he had learned to recognize various phases of gout in the system, and not to look to uric acid as the cause of all its symptoms. It was a relief to hear nothing about microbes, and that gout could be relieved by old-fashioned remedies with exercise. Dr. Fortescue Fox said we must distinguish between acquired gout, which was a diet disease to be treated by diet, and hereditary gout, which was not relieved by dieting. Dr. Ewart said the essence of gout was functional, but it passed into a structural disease. The offspring of gouty parents should be treated with a view of preventing structural changes.

Dr. Luff threw down the gauntlet against the "fetich of uric acid," which, he said, was in no sense a poison, but a comparatively harmless by-product. The liver could convert uric acid into urea to a certain amount, but that amount had no part in the pathology of gout, which was an autointoxication, and might be due to the bacteria of the intestines becoming altered so as to give off the toxin of gout. The liver could destroy that toxin, but if its function fell below par the undestroyed toxin would produce gout.

At the Clinical Society, on the 14th inst., Mr. Moynihan read a paper on "Mimicry of Malignant Disease of the Large Intestine." He related six of these puzzling cases upon which he had operated. In all, a diagnosis of malignant disease had been decided on before or at the time of operation, and yet this was incorrect. In one there was a growth blocking the rectum; in another a tumor of the sigmoid flexure; in two others inflammatory tumor due to pericolitis; in another a tumor with a number of diverticula, one of which had perforated, but no evidence of malignancy; in the other an inflammatory tumor of the splenic flexure, which disappeared after a short-circuiting operation. Mr. Moynihan remarked that mimicry of malignant disease about the cecum and ascending colon by a hyperplastic tuberculous process was pretty well known. He had operated on two such cases in the belief that they were cancerous, but it was not so generally recognized that inflammatory tumors with all the clinical appearances of cancer attacked all parts of the large intestine. Many of them, he thought, might be due to false diverticula.

The president, Mr. Clutton, recognizing the importance of the paper, compared the cases with those of gastric tumors supposed to be cancer, but which disappeared after gastroenterostomy. He was very skeptical about the syphilitic nature of rectal cases so commonly assumed. Dr. Brook related a case operated upon for acute obstruction when a fixed tumor of the cecum was found. Short-circuiting was done, and eighteen months afterwards the man was well, and no sign of the tumor was detected. Mr. Spencer had operated on a similar case, and seven years later at the post mortem the intestine was found normal. He suggested that many cases that recovered after exploratory operations were of this nature. Mr. Moynihan, in reply, thought syphilitic cases could often be distinguished, though in one of those related there had been a mistake. In literature he had found forty cases of diverticula. In museums he had seen forty specimens described wrongly as syphilitic.

Two cases of ruptured diaphragm, with accompanying severe injuries caused by squeezing between railway buffers, were then read. The first was by Mr. J. Berry, and his patient, a railway man of nineteen, was admitted soon after his injury in a state of profound collapse. The physical signs pointed to rupture of lung, and blood and air in the pleura. It was also thought that the diaphragm had been ruptured. For three days he continued collapsed, the heart being pushed more and more to the right, and signs of strangulation set in. In this desperate state it was thought best to open the abdomen and attempt to reduce the strangulation. On doing so a large rent in the left posterior part of the diaphragm was found, through which most of the stomach, colon, and omentum, upper end of left kidney, and half the spleen (which was cut in two) had passed into the thorax. The herniated viscera were with difficulty drawn back into the abdomen and the operation completed by closing the rent, partly with sutures and partly by fixing the liver. The patient died almost immediately.

The other case was read by Mr. J. P. Roughton. The abdomen was opened the day after the injury, and the stomach, which had passed high into the thorax, was withdrawn, blood coming from the chest into the abdomen. The patient died the next day. At the post mortem the diaphragm was seen to have been torn away from its attachment between the ensiform cartilage and ninth rib; there was a rent in the spleen, probably the source of the blood mentioned above. The delay in this case of serious symptoms made it a more favorable one for an attempt to deal with it. The great interest of the cases was commented on by the president and others, and the authors congratulated on their efforts, which seem to show how perhaps surgery may yet accomplish something in these terrible cases.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE APPOINTMENT OF PROF. ALBARRAN—THE TREATMENT OF CANCER—INVESTIGATIONS ON TUBERCULOSIS IN SCHOOL CHILDREN—THE SURGICAL TREATMENT OF HEMATURIA—ABDOMINAL HYSTERECTOMY FOR CANCER OF THE CERVIX—RADIOTHERAPY IN THE TREATMENT OF CARCINOMA—THE REMOVAL OF TATTOO MARKS—A WORK ON DIETETICS.

PARIS, December 15, 1906

THE chair of Diseases of the Urinary Organs having become vacant in the University of Paris in consequence of the retirement of Prof. Guyon, who has reached the age limit, Dr. Albarran has been appointed as his successor. The very considerable and important advances made by Prof. Albarran in all branches of this specialty, as well as his favorable reputation in other countries made it seem quite natural that he should receive the appointment. His first lecture was held on November 14, before a large audience assembled to welcome the new head of the well known Ecole de Necker.

Several of the recent sessions of the Académie de Médecine have been devoted largely to the question of the treatment of cancer. Prof. Poirier is firmly convinced of the curability of cancer by the resort to early and extensive surgical intervention. While it is true that the nature of carcinoma is still entirely unknown it is certain that the disease is at first local and remains so for a longer or shorter period of time, and during this time is curable by widespread excision. According to M. Poirier, no serum has ever cured a single malignant growth. As for radiotherapy, which to be sure has a specific action in regard to certain superficial cancers, no cure of a deep cancer can be credited to it. The speaker also insisted on its especially deplorable effects in cancer of the tongue. At first pain is relieved and the glandular enlargements are reduced in size, but the process continues in the deeper parts and the condition has already become inoperable when the patient finally abandons radiotherapy in order to consult the surgeon. The speaker concluded by saying that it was greatly to be regretted that there was not in France an institute for cancer research like those of Germany and England.

Prof. Berger also affirmed that surgical operation is still

the only remedy by which cancer may be cured. Medication and serum therapy were both ineffectual, and radiotherapy was of value only in the very superficial forms, but even operation gave results only under very restricted conditions and its benefits were sometimes uncertain. Like the preceding speaker, Prof. Berger proposed the organization of a scientific committee for cancer research which should centralize and direct investigations in this field. Prof. Cornil also spoke in favor of this idea and said that the cancer institute should possess a laboratory for histological studies and another for experimental work.

Prof. Grancher submitted to the Académie the result of his investigations on adenopulmonary tuberculosis carried out in the schools of Paris. He said that during the past three years he had made systematic examinations on more than 4,000 school children. He considered that adenopulmonary tuberculosis in children was curable, but only under certain favorable conditions. It was necessary to begin the treatment in the very earliest stages of the disease. He had been able to detect it in its first beginnings in from 15 to 16 per cent. of the Parisian school children. It had been found that the treatment tried in the schools of giving the children an extra meal of meat extract and cod liver oil was not sufficient. It failed to do more than to keep the condition from progressing in the majority, while it did not prevent some from becoming growing worse. It was therefore necessary to assist the parents of the child and this might be done in two ways. Children suffering from slight degrees of tuberculosis and not throwing off bacilli might be placed in country families who would be informed that the child was sick and would be paid a sufficient amount to secure adequate care and proper feeding for it. Under these conditions the child should be under the care of a physician who would be able to determine when the tuberculosis became infectious and the patient should be removed. The other method was considered preferable by M. Grancher and consisted in placing the children in a school sanatorium in the country under medical supervision.

At the recent meeting of the Société de Chirurgie M. Pousson of Bordeaux discussed the surgical treatment of renal hematuria. The author advocated the conservative operations, comprising nephrotomy, the nephrolysis of Rovsing, and the decapsulation of Edebohls. In his opinion simple incision of the kidney had a very beneficial effect. Unfortunately the patients who have been subjected to simple decapsulation have not been under observation a sufficiently long time to determine the value of this procedure.

M. Jean Louis Faure reported the result of his experience in the treatment of cancer of the cervix by abdominal hysterectomy. He had performed this operation forty times; eighteen of the patients had been kept under observation, and of these ten had suffered recurrences, whereas several others appeared to have been permanently cured. The author employed the technique of Wertheim. Out of twelve patients who had survived the operation nine had remained without recurrences for a period of time varying between fourteen months and four and a half years. The operation was long, difficult, and fatiguing, but the results appeared to recompense the surgeon largely for the pains he took. Faure believed that by operating early and carefully still better results could be obtained, and that perhaps cancer of the cervix would come to be in the same class with cancer of the breast.

The treatment of cancer by radiotherapy was considered by the Société Médicale des Hôpitaux and M. Beclere offered the following conclusions: In dealing with a subcutaneous new growth, and especially a new growth of the breast, of which the nature was still uncertain, the physician could not do better than to obtain the advice of a competent surgeon, but in all cases where operation was either voluntarily deferred by the surgeon or refused by the patient it was the duty of the physician to resort to radiotherapy rather than to lose precious time by the use of so-called resolving ointments or other equally ineffectual measures.

An interesting procedure for obliterating tattoo marks was described by M. Variot. The patient was a man of twenty-five years who had two tattoo marks on his left forearm, one anteriorly representing a naked female and the other on the posterior surface. On account of the indecency of the pictures the man, who was a laborer, was unable to find employment, and accordingly he was very anxious to be relieved of his adornments. Variot resorted to the method of cauterization by means of tannin and silver nitrate. For this purpose a bundle of needles was used to pierce the skin to the same depth as was done in performing the tattooing, and in this way the solution of tannin or silver nitrate was enabled to penetrate to the layer where the pigment particles had been deposited. Two months after the termination of the treatment one saw only a slightly pigmented scar, brownish in color, and not very conspicuous. The skin of the region was soft and moved readily over the aponeurosis. Another procedure was suggested by M. Danlos, who recommended the repeated application of blistering agents, but he said that the ideal method was electrolysis, by means of which it was possible to destroy the tattoo marks very rapidly without leaving any visible scar.

An interesting book entitled "Les Aliments Usuels," by Dr. A. Martinet, has recently appeared. It is intended to place within reach of the general public modern ideas on the subject of rational dietetics. The first part is devoted to the study of the fundamental foodstuffs and to a description of the methods employed for their chemical and physiological investigations. The author then describes the separate foods in detail and discusses their value in health and in disease.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

NEW BERLIN HOSPITALS—THE HEART IN GOITER—THE MODE OF ACTION OF GASTROENTEROSTOMY—A RARE BLOOD DISEASE—EXPERIMENTAL KYPHOSIS—ELECTRIC OPHTHALMIA—THE MEDICAL TREATMENT OF PROSTITUTES.

BERLIN, December 18, 1906.

DURING the past few weeks most of the Berlin physicians have been inspecting the various new hospitals. The Rudolph Virchow Hospital especially is proving a great center of attraction for visitors, and with its beautifully-laid-out grounds shows to its best advantage in these delightful autumn days. Only 300 of the 2,000 beds are now occupied, but one can already gain an adequate impression of this enormous institution which is especially interesting to visit since the directors themselves conduct sightseers through the buildings. Recently the new hospital of the suburb Pankow has been opened, which, though small, is planned so that it can be enlarged to a capacity of 400 beds and possesses all the facilities of a modern hospital. It is expected that the much larger Schoenberg Hospital will be ready for occupancy this year, and it seems as if in the near future it would no longer be possible to speak of a scarcity of hospital accommodations in Berlin.

In the first session of the Verein für innere Medizin Kraus read a paper on the condition of the heart in goiter. He stated that the relations of the thyroid gland to heart action could be toxic or mechanical. Three chief varieties of etiological factors could be distinguished. First, those present in exophthalmic goiter, second in struma, and third in artificial hyperthyroidism. In these cases tachycardia might be present, with a heart beat of from 80 to 120 while at rest, and 140 after exercise. The tonus of the vessels was diminished, but the blood pressure was often somewhat elevated. Staring eyes, wide pupils, exophthalmos, sweating, tremor, and dermatographia were usually present. A partial strumectomy was generally effective in giving relief and iodine was a valuable remedial agent. The term "Formes frustes" of exophthalmic goiter applied by Charcot to this condition of the heart was a bad one, and Kocher's expression "equivalent of exophthalmic goiter" was better. The fact that in some cases the condition remained a local equivalent, while in others real exophthalmic goiter developed, depended on individual conditions, as had been shown by the experimental feeding of thyroid extract to animals.

Katzenstein addressed the same society on the effect of gastroenterostomy on gastric ulcer and gastric carcinoma. He believed that the beneficial effect of the operation was due largely to the improvement brought about in the motor function. In order to investigate the causes of this action he performed gastrostomy on seven dogs that had been subjected to the operation of gastroenterostomy. The speaker stated that the action of pepsin was inhibited in an alkaline medium, but that trypsin, even after having been subjected for twenty-four hours to the action of hydrochloric acid and then being rendered alkaline, did not lose its potency. That was why, after gastroenterostomy, in which the bile and pancreatic juice entered the stomach, the food could still be thoroughly digested. On introducing food into the stomachs of dogs that had been subjected to gastroenterostomy the speaker stated that a diminution in acidity could be detected one and a half hours later, and if meat and fat were given, after even half an hour. He made artificial ulcers in the stomach and intestines and dabbed them with hydrochloric acid. The gastric ulcers in these dogs were cured through the alkalinization of the gastric juice, but those of the intestine went on to perforation. The prolongation of life that often occurred in carcinoma after gastroenterostomy was explained by the speaker on the assumption that the carcinoma was digested by the trypsin.

At a meeting of the Medizinische Gesellschaft, held on

October 24, Senator read a paper on a rare disease, of which only a few cases have been observed, and which is called polycythemia rubra megalosplenica. The disease, he said, was characterized by a dark coloration of the skin, erythrocytosis, and splenic enlargement. In the two cases observed the red blood-cells were increased to six to ten millions per cmm. In its other characteristics the blood was normal, though the blood pressure was raised somewhat. The causes of the erythrocytosis were either a diminution in the destruction of the red cells or a stimulation of the hematopoietic organs. In favor of the latter view was the fact that in three cases of the disease hyperplasia of the bone marrow was reported. It was possible that the spleen produced stimulating substances which gave rise to the polycythemia.

A new subject for experimental research was suggested by a paper on experimental kyphosis recently read by Munk at a meeting of the Physiologische Gesellschaft. This investigator was able by various operative procedures to produce spinal curvatures of various types in monkeys and described the method of causation of secondary palsies of the extremities and the lesions of the spinal cord produced by these measures.

Czellitzer read an interesting paper on electrical injuries before the Medizinische Gesellschaft. This paper should prove of interest in all countries where electricity is largely used for industrial purposes. Thirty-two employees in a foundry where welding was done by means of a powerful electric current which gave out an intensely brilliant light were affected with electric ophthalmia, so called, although they simply passed by the source of light at a distance of fifteen or twenty feet. The patients awoke during the night suffering from pain in the eyes, the lids became swollen, the eyes could not be opened, and photophobia, epiphora, and swelling of the conjunctiva were present. The condition was relieved after several days of treatment by boric acid compresses. The speaker pointed out that in this case the workmen simply passed by the source of light without looking at it, and yet they were affected. He assumed that the disease was caused by the ultraviolet rays and not by the red light rays.

The Berlin police officials have been planning for a reform which will do away with an abuse of long standing. It is the duty of the police department to supervise the treatment of all prostitutes who become diseased. Many of these women avoid treatment because they are obliged to go to a special hospital and are kept under observation for a long period of time. On this account the danger of spreading venereal disease is great, and, besides, sojourn in this special hospital and association with old offenders serves to complete the demoralization of those for whom otherwise there might still be hope of reform. The police department has secured the services of specialists in venereal diseases who will treat such women gratuitously. Under these conditions the patients will not be required to remain under police observation. The physician's certificate will be sufficient to relieve the women from the necessity of being under surveillance and of entering the special hospital.

Progress of Medical Science.

New York Medical Journal, December 29, 1906.

Errors in the Treatment of Cutaneous Cancer.—A. R. Robinson refers to the many plans of treatment which have had their run and are now forgotten. He has seen no noticeable benefit from the use of thyroid extract in visceral cancer. Toxins, sera, etc., are useless. He describes the methods he follows in cancer in the various bodily areas, holding that that method of treatment is best which removes with the greatest certainty all of the pathological tissue, even if the resulting deformity is greater than that caused by some other less effective method; and that of two methods offering equally good results as regards a cure, there should be employed that one which would cause the least deformity, when deformity from a cosmetic standpoint must be considered. The comparative effects of the various caustics are fully described. The author says concerning the *x*-ray that it is a decided addition to our armamentarium against cancer, but its virtues have been overexploited by some writers, perhaps for reasons best known to themselves. It is a grave error to maintain that with the *x*-ray alone all cases of cancer of the skin can be cured. This is not even true of cancers seen in a very early stage. It is also an error to hold that in all such cases where it could effect a cure it is the best agent to be employed. He believes its exclusive use should be limited to a very few cases out of all those that come under observation, such as those of rodent ulcer and some cases of superficial prickle-celled epitheliomata. In closing, the author calls attention to the following principles: All cases of multiple cutaneous cancer and all aged persons with cutaneous cancer require internal treatment in the form of diet and drugs in addition to local measures. A diet of milk and green vegetables and the avoidance of meats in general and of meats of such organs as liver and kidneys in particular, and the avoidance of alcohols, is advisable in all cases of cancer, whether external or internal. Thyroid extract should be given in as large doses as can be borne in all cases where there is a senile condition of the skin and in most superficial epitheliomata. A knowledge of the kind of cancer present, the pathological anatomy, and the manner of extension of the disease in general and of the special variety of the case to be treated is necessary to a correct choice of method of treatment. When possible all cases should be under observation at least one year after commencing treatment of any kind, in order to treat promptly any recurrence of the disease. Early diagnosis and correct treatment place cutaneous cancers among that class of diseases, which do not deserve the name of incurable diseases, as almost without exception they can be treated successfully if the method employed is the correct one.

The Physiology of Language and Its Relation to the Treatment of Stammering.—G. H. Mackuen defines stammering as a more or less constant inability to speak freely owing to an incoordinate and spasmodic action of the respiratory phonatory or articulatory muscles. It is a very common affection. One per cent. of school children stammer. The author describes the methods followed in the analysis of the fundamental sounds of letters as used in speech, and shows how it is necessary to construct an alphabet of sounds which shall bear the same relation to speech that the English alphabet of letters bears to writing. He presents a tabulated "physiological alphabet" thus constructed. The use of such an alphabet in the treatment of stammering serves as a mental, as well as a physical, discipline. Just as a child learns to read one short word or syllable at a time, so the stammerer should be taught to phonate or articulate one short word or syllable at a time. This process is known as syllabication. Attention is also called to the physiological division of words into syllables for the purpose of syllabication. They should be divided, not according to their etymology, as you find them in the dictionaries, but according to their physiological enunciation. For instance, we say phy-si-o-lo-gi-cal, not physi-o-log-ic-al, and e-ty-mo-lo-gi-cal, not et-ym-ol-o-gic-al. This is the natural or easy way to pronounce words, and we take advantage of the fact not only by calling the attention of the stammerer to it, but by practising him in the art of doing it. We also teach him syllabication by having him read the elements of language as they appear in sentences. This is called phonetic reading.

Eyestrain as a Cause of Headache.—Linn Emerson says that eyestrain is the cause of insomnia, vertigo, nausea, neuralgia, migraine, and failure of general health, and has but scant patience with those who believe otherwise. He believes that more than half the cases of so-called bilious or sick headache are due to eyestrain, and that many cases of the above named nature are referable to the same cause. He also finds that another class of cases frequently failing to receive proper treatment are the early presbyopes. The individual with normal eyes and health goes to the age of forty-five before glasses are required for near work. But if there is moderate impairment of health or latent hyperopia present, the patient begins to have headaches at forty, or even sooner, and for various reasons the eye condition is overlooked. One of the principal reasons why the eye condition is often overlooked is because the mind of the layman associates the use of glasses for near work with oncoming senility, and as a woman is only as old as she looks and a man as old as he feels, the imputation that the patient is getting old is sharply resented. That the power of accommodation fails rapidly after the age of twenty-five is unknown to the patient, and to say that they are presbyopic or old-sighted is an unpardonable breach of courtesy. There is such a condition as premature presbyopia, and in many instances we are obliged to give glasses for near work to patients even in the twenties. Among women all the head symptoms occurring between the ages of forty and fifty are generally attributed to the menopause. Many of these cases would be markedly relieved of their troublesome head symptoms by the use of proper glasses for near work.

Divers' Paralysis with Scarlet Fever.—R. Ellis reports the case of a civil engineer working in compressed air who had a sudden attack of acute myelitis. There was complete loss of sensation and motion from the nipple line down, with partial paralysis of the diaphragm and entire loss of temperature sensation. There was partial paralysis of arms and neck, so that his hands, arms, and head were not under control. There was complete paralysis of the bowels and bladder. His mental condition was normal. Two days afterward an expert in spinal diseases gave a bad prognosis and ordered no treatment. His temperature ranged from 99° to 102°, pulse about 90. On the fourth day scattered red points appeared about both elbows. On the fifth day there was quite intense hyperemia of the skin of the entire body looking like scarlet fever rash. The throat was not sore, but slightly red; the tongue was coated with red edges. There never was nephritis, but cystitis developed early. There was complete desquamation. There were severe rheumatic pains in left shoulder and elbow nad left knee joints. There were no other complications. Three experts made a positive diagnosis of scarlet fever and as a result the patient, with four attendants, was isolated for six weeks in the hospital garret. No other case of rash developed among 250 patients who were exposed. The author says that further study is called for to determine whether the rash attending some cases of myelitis is really scarlet fever or an acute exfoliating dermatitis.

Journal of the American Medical Association, January 5, 1907.

Lupus Vulgaris.—Two cases of lupus of the ear, illustrating the serious nature of the disorder, are reported by A. Ravogli. In both, the tubercle bacillus was found in the extensive ulcerations destroying the external ear, and in one the disease had deeply involved the underlying bony and other tissues. He remarks that connective tissues, bones, and fascia do not have the resisting power to the tubercle bacillus that is possessed by the skin, and when the germ gets away from the latter it is no longer under control, and in a short time the disease is reproduced in a nodular or disseminated form which represents miliary tuberculosis of the intestinal organs. Lupus therefore is always a serious disease, and prognosis should be guarded in any case. In these cases treatment was discouraging; the Finsen method failed, though it was at first apparently helpful in one case. The best results, so far, were obtained by applications of pure lysol, which forms a hard whitish eschar, followed by healthy cicatricial tissue. The article is illustrated.

Cancer-Infected Cages for Rats and Mice.—H. R. Gaylord and G. H. A. Clowes give the history of the endemic occurrence of sarcoma in rats in an infected cage in the New York State Cancer Laboratory. Three years previously the cage had been used for the keeping of rats inoculated with sarcoma. They also give an account of another infected cage in which, in the course of three years, over sixty cases of carcinomatous tumors have occurred in white mice. The frequent changes of location of the cage and of its occupants in at least one instance without interrupting the occurrence of tumors seem to leave no doubt that the infection is in the cage. The authors consider it the most striking example of cage infection that has yet been recorded. These observations, they remark, indicate that both sarcoma in rats and carcinoma of the breast in mice (all the cases in the mice seemed to occur in females), must be looked on as contagious, and, taken in conjunction with other like observations on record, should, they think, lead us to give more consideration to the possibility of the contagion or local infection of malignant growths in the human species.

Migrainic Psychoses.—Alfred Gordon reports twelve cases of migraine associated with mental symptoms, observed within the last four years, and all presenting similar types of derangement, namely, confusion, delirium, usually with hallucinations, and stupor. The hallucinations were usually visual, though gustatory and auditory hallucinations were also observed. The confusional stage predominated in all, and was frequently accompanied with illusions of identity, incoherence and disturbance of orientation. Some of the cases suggested psychic epilepsy or procursive epilepsy. In the majority of cases the mental symptoms occurred during the attacks, and in some they continued twenty-four hours after the subsidence of the migraine. In some cases, however, they occurred either before or after and they lasted in some cases for twenty-four hours after the subsidence. He does not think that he can explain these conditions as epileptic or hysterical, though in some cases they suggested it. The special point is their association with an autotoxic condition, which is the basis of migraine.

Atrophic Rhinitis.—G. L. Richards reviews some of the more recent literature and theories of this disease. He finds little support in the facts for the theories that have been advanced of its etiology; that it is secondary to accessory sinus disease, that it is dependent on special conformation of the parts, that it is due to excessive dryness of the atmosphere, or that it follows the purulent rhinitis of childhood. It has not been proven in any case that the bacilli that have been found in the lesions or atrophic rhinitis are responsible for anything more than the odor of the disease, and Richards is inclined to think the view of Cozzolini, that it begins primarily in the bone, as an atrophy of the medullary blood-vessels, becoming later a periostitis or a rarifying ostitis, and the microorganisms play only a secondary part, as the most reasonable of all which have been advanced. The etiology is as yet an undetermined one and a subject for further study. There seems to be a predisposition, sometimes apparently hereditary, but just what constitutes this predisposition is undetermined. The various measures proposed for the treatment are reviewed and the result is rather discouraging. When all is said and done, the local therapeutics, he says, seems to reduce itself to a thorough cleansing of the nasal mucous membrane, and the use of any application which produces a mild stimulation is probably as effective as anything. The severer remedies do not seem to have any advantage over the milder ones. He hopes that a specific may yet be found and that the future will give a successful treatment. Notwithstanding his pessimism as to perfect cure, he always tells patients that they can be improved, which is true, and that with careful self-care they can keep the nose free from crusts and have a reasonable degree of comfort with it. In a few cases in which he has been able to control the treatment for a sufficient length of time in young persons, it seems to him that he has brought about a cure.

Digitalis Heart Block.—A. W. Hewlett gives the history of a case in which the use of digitalin was followed by slow and irregular pulse, the irregularity consisting in a dropping of the beats accompanied with precordial distress. Auscultation showed that the dropping was not due to the occurrence of extra systoles, but that during the intermission there was either absolute silence or at most only a faint and indefinite soft sound over the base of the heart. Simultaneous tracings from the veins of the neck and the apical region showed two forms of irregularity, the first due to a blocking of the cardiac contraction wave passing from the auricles to the ventricles, while in the second form the beat was also dropped out, but there was no auricular pulsation in the pause of the ventricular rhythm. He discusses the mechanism and causes of these phenomena and assumes the probability of a block occurring above the auricles as well as at the auricular ventricular septum.

The Lancet, December 22, 1906.

Heart Massage as a Means of Restoration in Cases of Apparent Sudden Death.—An analysis of 40 cases is made by T. A. Green. From the tables presented we learn that there are records of 0 successful cases and of 8 partially successful cases; that is, cases in which life was prolonged for periods ranging from two to twenty-four hours. Epitomized histories of the 40 cases are given. The author makes the following statements: (1) It has been possible in human beings to restore the heart beat by massage when ordinary measures of resuscitation have failed, even when the massage has not been commenced until the heart had been stopped for forty-five minutes, but a definite and complete cure has never yet been effected when this interval has been longer than from seven to eight minutes. (2) In many of the cases the adoption of massage for a period of from thirty seconds to five minutes has been sufficient to restore the heart beat, but it has sometimes been necessary to go on with it for fifteen minutes, or even longer. (3) Artificial respiration and its adjuncts must also continuously be applied, and sometimes it is necessary to persevere with it long after pulsation is restored in order to reestablish the respirations. For cases, therefore, of sudden heart and respiratory failure, he lays down the following order of procedure: (1) Immediate

lowering of the head and the commencement of artificial respiration and tongue traction, taking care that a free access of air to the lungs is possible and therefore implying tracheotomy if necessary. (2) If the abdomen is open, pressure on the abdominal aorta to confine the circulation to the upper part of the body. If it is not open the intravenous injection of adrenalin solution and the application of Crile's rubber suit or, failing this, tight bandaging of the limbs and abdomen. (3) The subcutaneous or intravenous injection of normal saline solution, partly to raise the blood pressure and partly to dilute any poisons which may be in the blood and tissues. (4) If the above methods have not been successful after being applied for from eight to ten minutes heart massage by the subdiaphragmatic method. This route should always be adopted, unless the chest is already opened or to be operated upon, as being the easiest way of access, the one fraught with least danger to the patient, and the one which has given the greatest percentages of success. The time is fixed at from eight to ten minutes because eight minutes is the limit of the interval at which up to the present time a complete success has been obtained in man, and if it is exceeded the danger of the production of fibrillary twitchings, inability to restore consciousness, and the development of spasms in the voluntary muscles with consequent failure of the manipulations have to be taken into consideration. The unavoidable extension of this limit should, however, be no bar to the adoption of the method, as very hopeful results have been obtained, even when forty-five minutes have elapsed from the onset of the syncope before it has been tried. (5) After normal pulsation has returned to the heart, artificial respiration must be continued until spontaneous breathing has been restored or until circumstances make it improbable that such restoration will be obtained.

An Operation for the Cure of Prolapsus Ani and Internal Hemorrhoids.—After some general observations D. Newman describes the operation, the object of which is to cauterize the mucous membrane of the rectum into six narrow strips from above downwards, each strip being four inches long by a quarter of an inch to one-sixth of an inch broad. This is done through a fenestrated speculum six inches long, four inches in circumference, and one and a quarter inches in diameter, with six windows four inches long and one-sixth of an inch broad. When the speculum is inserted fully the lowermost limits of these windows is half an inch above the anus, so that the mucocutaneous line is protected from the cautery. A general anesthetic having been administered, the patient is placed in the lithotomy position with the knees well raised and the hemorrhoids or prolapsed rectum is fully reduced. Then, having explored the passage with the finger, the fenestrated speculum containing the obturator is introduced to its full length; the obturator which prevents the mucous membrane from protruding into the lumen of the speculum during the introduction is then withdrawn. When light is reflected by a forehead mirror into the speculum the congested mucous membrane is seen protruding through the six openings in the speculum, the disc is then passed into the speculum to close the upper end of it, in order to prevent the mucous membrane at the end of the speculum from being accidentally scorched by the cautery. All the mucous membrane which protrudes through the opening of the speculum is freely cauterized with an iron cautery at a dull-red heat, and, if necessary, the speculum is cooled by allowing a stream of water to play upon its interior for a few seconds between each application of the cautery. When the operation is completed six narrow strips of cauterized mucous membrane are seen, the surface of which is almost level with the metal of the speculum. The disc is now withdrawn; a half-grain morphine suppository is introduced and the speculum is firmly packed with gauze covered with vaseline, and against the outer end of the gauze the obturator is held, and over it the speculum is withdrawn. The gauze tampon is retained within the rectum, its free end alone showing at the anus. The after-treatment is small doses of opium by the mouth and very limited diet for a week, so as to give the lower bowel complete rest during that time. The external parts are kept well cleansed, the tampon is retained till it causes uneasiness, and on the seventh day a laxative is given. The instruments above referred to are figured in the original article.

The Influence of Calcium Chloride on the Agglutination of Vibrios. The results of further observations by M. Crendiropouls and C. B. S. Amos are presented in tabular form. Their methods are described and their conclusions are given in the following language, their work being confined to vibrios obtained from choleraic and dysenteric stools at various Egyptian localities, notably El Tor: (1) Chloride of calcium greatly favors the agglutination of the vibrios usually considered to be those of true cholera. (2) On certain other vibrios which, though agglutinated by the so-called cholera serum yet without all the so-called specific characteristics of cholera vibrios, the effect of the calcium salt agglutination was very slight. These latter vibrios, while agglutinated by the serum, were hemolytic and did not fix the immune body of cholera serum.

British Medical Journal, December 22, 1906.

The Exanthem of Scarlet Fever and Some of Its Counterfeits; Clinical Significance of Skin Hemorrhages in Diphtheria.—These topics receive an interesting consideration by J. MacCombie, who discusses the scarlatiniform rashes seen at times in measles, variola, varicella, in enteric fever, scalds, etc., and in diphtheria following antitoxin injections. He points out the factors of differential diagnosis, noting, with special reference to German measles, the absence of the purely erythematous rash of scarlatina and observing that the spots are to be found on the face as well as on the trunk and extremities. On the trunk the individual macules are larger than the fine punctations of scarlatina in the same location. On the forearms and legs the scarlatinal rash is frequently papular, and the individual spots may be as large as the head of a good-sized pin, but this characteristic does not obtain of the rash as a whole. Skin hemorrhages in diphtheria signify a pretty general toxemia. The author has noted a little over 200 cases in a total of 6,755 diphtheria patients. None were seen in cases brought under treatment on the first day of the disease. The patients have practically all been under twelve years of age, and the hemorrhages have been rather more common below than above the seventh year. They are more marked on areas subject to pressure, but are by no means limited to such areas. They are more common in severe faucial diphtheria with which nasal involvement is associated. In pure laryngeal diphtheria they are rarer. The areas most frequently involved are the trunk and extremities, but they may develop on the face, ears, and neck. As a rule the number of spots does not exceed six. There may be in addition scattered red petechial spots. If only one or two hemorrhagic areas are present, the patient may recover; but if there is a greater number, the case is nearly always fatal. For this reason they afford a most valuable aid to prognosis which it is wise not to overlook. In some of the cases persistent epistaxis precedes or accompanies the appearance of these skin signs. Incidentally the occurrence of persistent epistaxis about the fourth or fifth day of faucial diphtheria leads one to anticipate the very probable occurrence of skin hemorrhages within a short time thereafter. Hematemesis is sometimes present, due in many cases to hemorrhage from the mucous membrane of the stomach. Persistent vomiting and signs of cardiac failure are to be noted in most cases showing skin hemorrhages, the patient dying of toxemia and cardiac failure. The duration of life after the date of onset of the skin hemorrhages is usually four or five days, sometimes less, while some cases live for a week or a fortnight. In preantitoxin days patients hardly ever survived more than two days after the skin hemorrhages appeared. Cases which recover are those in which vomiting and cardiac failure are absent, or are little in evidence.

Berliner klinische Wochenschrift, December 17, 1906.

The Successful Removal of a Tumor of the Occipital Lobe of the Brain.—Oppenheim and Krause describe this case in which a tumor of unusual size was removed from the occipital lobe of the brain. The patient was a man of thirty-five years, who, after suffering for some weeks from headache, developed right-sided hemianopsia, optic neuritis of the right eye, vertigo, vomiting, bilateral choked disc most pronounced on the right side, and partial alexia and agraphia. A little later right-sided hemihyperesthesia, hemiataxia, and hemiparesis developed. Iodine and mercury as well as other internal remedies proved without effect, and as it was believed that from the clinical signs the tumor could be located in the occipital region of the left side, operation was decided upon and performed in two stages three and a half months after the onset of the headache. At the first stage a large quadrilateral bone flap was made over the occipital lobe, exposing the lateral and longitudinal sinuses. Sixteen days later

the wound was reopened and the dura incised. The tumor could be immediately seen occupying the lower median angle of the opening made, and it was easily removed by blunt dissection. It measured 32x55x58 mm., and was egg-shaped. On microscopical examination it was found to be a spindle-celled sarcoma. The operation lasted only one-half hour and there was little loss of blood, but during several days the patient was in a very precarious condition owing to high temperature and rapid and feeble heart action. He ultimately recovered completely, however, and has been able to go about his business as well as ever, the only symptoms persisting being a moderate contraction of the right visual field, while otherwise he is entirely free from difficulties.

A Gigantic Renal Calculus.—Johnsen says that the largest kidney stone removed by operation heretofore reported is one described by Sheild in the *Lancet*, October 15, 1904. This stone, which weighed 570 g., had a length of 13 cm., and its largest lateral circumference measured 26 cm. A calculus recently removed by Pelz surpasses this specimen in size, though not in weight, as it measured 14.1 cm. in length, and its largest longitudinal circumference was 33.5 cm., and the largest lateral circumference 28.5 cm. Its surface was extremely irregular and, owing to the very dense fibrous tissue growth its presence in the kidney had evoked, the removal of the stone, together with what remained of renal substance, could be effected only with the greatest difficulty. The patient made a good recovery.

Münchener medizinische Wochenschrift, December 18, 1906.

Immunity in Mice Against Carcinoma.—Schöne describes experiments made in Ehrlich's laboratory to determine whether by injecting emulsions of various organs it is possible to render mice refractory to inoculation with Jensen's mouse tumor. Experiments with mouse liver, mouse testicle, and chick embryos seemed to confer a slight degree of immunity, though this was not very marked, but on using mouse embryos a very pronounced grade of immunity could be obtained. A moderate degree of immunity was also secured by injections of human carcinoma of the breast. Schone considers that these experiments as well as Bashford's similar results with the injection of mouse blood are sufficient to overthrow Doyen's belief that carcinoma immunity is bacterial and that the *Micrococcus neoformans* is concerned in the process.

Three Cases of Neuralgia of the Tongue.—Hoeflmayer says that neuralgia of the tongue is extremely rare, and yet in the last year he has seen three cases of the affection. All of the patients were men, moderately neurasthenic and suffering from chronic constipation. In none of the cases were either the glossopharyngeal or hypoglossal nerves affected. The pain involved only the domain of the lingual nerve, and the anterior third of the tongue which is supplied by the chorda tympani was not included in the painful area. In each case cure was effected by relieving the tendency to constipation, and the author ascribes the condition to the absorption of toxins from the intestines.

Deutsche medizinische Wochenschrift, December 20, 1906.

Diagnostic Difficulties in Regard to Incarcerated Femoral Hernia. Haberern calls attention to the many different conditions, such as hydrocele, testicular swellings, enlarged glands, abscesses, etc., that may simulate hernias, and that have led to wrong diagnoses, but speaks particularly of varicosities of the saphenous vein in connection with femoral hernia. He himself was led into error in dealing with the case of a woman of forty-nine years who presented what appeared in all ways to be the typical picture of an incarcerated femoral hernia accompanied by the usual symptoms of sudden onset of painful swelling, nausea, vomiting, and constipation. Some years previously, on consulting a prominent gynecologist, she had been assured that she was suffering from hernia and a radical operation was proposed. This was refused by the patient and since that date she had worn a truss constantly. On cutting down upon the tumor, suddenly a tremendous gush of blood was poured out, and the true nature of the condition became evident. The saphenous vein was tied off together with the plexus of inflamed varicosities and the wound healed by primary union. At present, three years after the operation, there is no trace of either varicosities or hernia. The author states that while it is usually easy to distinguish varicosities from a reducible hernia, it may be a matter of the greatest difficulty to differentiate between varicosities and an incarcerated hernia, and he reports his case as an illustration of this fact.

French and Italian Journals.

Appendectomy Phlebitis of the Lower Left Extremity.—Broca refers to a case reported by Dieulafait. This patient, a man twenty-two years old, was operated upon after a third crisis of appendicitis. The operation was simple and easy, and healing was rapid without suppuration. Nevertheless, on the fifteenth day a small oozing of bloody fluid was noticed at the cicatrix, and the existence of a phlebitis of the left leg was discovered. Different interpretations of such a condition are given. Dieulafait thinks that perhaps it is due to the relative mobility of the left leg during the period of dressings and rest. Broca has observed several such complications following kelotomy practised on the right. He knows of no explanation for such an occurrence.—*Le Bulletin Médical*, October 20, 1906.

Electricity in the Treatment of Skin Diseases.—Augustino di Luzenberger says that electricity is beneficial to various forms of skin diseases, and in various forms or application. Among these are galvanism, electric cataphoresis, static electricity, and the *x*-rays. Cataphoresis is useful in the destruction of keloids, acne rosacea, erectile and cavernous angiomata by causing coagulation in them. The direct galvanic current produces dilatation of the vessels, and dissipates edema. The chief power of cataphoresis is a biological rather than a chemical one. There is cellular and trophic stimulation. Static electricity given in form of baths has a stimulating and tonic effect, and increases the activity of metabolism, assimilation, and elimination. It is useful in pruritus, urticaria, impetigo, and furuncles. It is used for varicose ulcers and for alopecia. The resonator of Oudin has a sedative effect on pruritus, stops the development of infective agents, produces transitory analgesia, causes vasoconstriction, and modifies inflammatory processes. It is useful in eczema, prurigo, lupus, acne, impetigo, etc. The value of the *x*-rays in lupus is well known.—*Annali di Elettricità Medica e Terapia Fisica*, September, 1906.

Abdominal Pregnancy with Fetal Retention Dating Back Twenty-one Years.—Bégouin observed this patient, a woman who at nineteen years of age had given birth to a child. At the age of twenty-four years she had a miscarriage of two months and a half, and at the age of thirty-three she had become pregnant again. At the third month of pregnancy she showed the grave symptoms of hematocele, which were repeated at the fourth month; nevertheless, the pregnancy continued. At the ninth month false labor occurred, with death of the fetus. The fetus remained twenty-one years in the abdominal cavity, causing only slight disturbance. Then extreme pain developed, with loss of sleep and appetite, which rendered life intolerable. Laparotomy was performed, and the fetus, which was very adherent to the maternal tissues, was removed. Three months after the operation the patient died from intestinal occlusion. The fetus was in an excellent state of preservation, showing no calcareous incrustation. An abdominal fetus ought to be extracted at the end of some months, or in the course of the first year, when the maternal adhesions are comparatively soft.—*La Tribune Médicale*, October 13, 1906.

The Heart in Basedow's Disease.—Guido Dernini gives the histories of fourteen cases of exophthalmic goiter observed by him, in which he made a special study of the condition of the heart. He sums up his observations for us thus: 1. The heart in Basedow's disease is particularly sensitive to fatigue, soon using up its reserve force. 2. There is slight increase in the diameters, especially the transverse, but they are transitory. 3. The amount of fatigue of the heart is in relation to the general asthenia of the patient. 4. The return to its original size is almost complete; in advanced cases of the disease the return may be slow and incomplete. 5. The murmurs heard in the disease are very variable, and change rapidly in a short period. The condition of the blood has no influence in the production of such murmurs. *La Riforma Medica*, October 27, 1906.

Calculous Anuria and Ureteral Catheterism.—Imbert has recently had under his care two patients suffering with calculous anuria who were cured by ureteral catheterism. In these two cases the sound reached without difficulty up to the pelvis of the kidney. From this fact the observer concluded that there is no reason for admitting the existence of mechanical obliteration of the ureter by a calculus acting like a simple plug. In one of the patients a simple vesical lavage sufficed to reestablish the course of the urine. It is probable that there existed a double reflex: the first, provoked by the contact of the calculus with the ureteral mucosa, determined the contraction of the subjacent muscular layer; the second, which succeeded the preceding, was the arrest of the renal secretion which was due not to the presence of the stone, but to the tension of the kidney. —*La Presse Médicale*, October 17, 1906.

Book Reviews.

An Introduction to Physiology. By William Townsend Porter, M.D., Associate Professor of Physiology in the Harvard Medical School. Philadelphia and London: J. B. Lippincott Company, 1906.

This Introduction to Physiology is a guidebook for work in the physiological laboratory; and as such will probably be found useful by those in need of help in this line. The book is divided into three parts: the first dealing with the general properties of living tissues, the second with the income of energy, and the third with the outgo of energy. In the preface the author calls attention to the "concentration" system as adopted in the Harvard Medical School. By this method the first half-year in the medical school is devoted to anatomy and histology, the second half-year to physiology and biological chemistry, the third to pathology and bacteriology, the fourth, fifth, and sixth to practical medicine and surgery; while the seventh and eighth are elective, each student choosing for himself the studies best suited to his needs. The present volume is a collection of fundamental and accessory experiments in several fields of physiological knowledge, printed in an abbreviated form for the temporary use of Harvard medical students and other interested persons.

Operationen am Ohr. Die Operationen bei Mittelohreiterungen und ihren intrakraniellen Komplikationen. Für Aerzte und Studierende, von Dr. B. Heine, a.o. Professor an der Universität und Direktor der Universitäts-Ohren-Poliklinik zu Königsberg i. Pr. Zweite, neubearbeitete Auflage. Mit 29 Abbildungen im Text und 7 Tafeln. Berlin: Verlag von S. Karger, 1906.

The second edition of this work is well fitted for practitioners and students desiring a knowledge of the operations relating to the ear. To the student familiar with the German language, this treatise is especially beneficial. Going into the minutest detail, the author has taken pains and succeeded in covering the field in two hundred pages of excellent printed matter. The description of the operations for acute mastoiditis and for chronic suppuration of the middle ear are particularly interesting. The book is divided into two parts: the first treats of the operations of the tympanum and attic, the mastoid operation, and the opening of the labyrinth; in the second part are included the operations for extra- and intradural and brain abscesses, sinus thrombosis, ligation of the jugular, serous, and purulent meningitis, lumbar puncture, etc. Seven photoengravings, illustrative of the various operations on the temporal bone, contain some of the best descriptive pictures of the intricacies and pitfalls of these operations.

The Treatment and Prophylaxis of Syphilis. By Alfred Fournier, Professor at the Faculty of Medicine, Member of the Academy of Medicine, Physician to the St. Louis Hospital. Paris. English Translation of the Second Edition (Revised and Enlarged), by C. F. Marshall, M.D., F.R.C.S., late Assistant Surgeon to the Hospital for Diseases of the Skin, Blackfriars, London, formerly Resident Medical Officer to the London Lock Hospital. London: Rebman Limited; New York: Rebman Company, 1906.

Dr. Marshall is to be congratulated on his skill in converting Prof. Fournier's brilliant French into clear and attractive English, and in shortening the text, not by omission of matter, but by condensation of form. This is made possible by the fact that the original volume on treatment was a series of lectures, and therefore somewhat full, while the volume on prophylaxis was a collection of papers written at long intervals and containing many repetitions. By judicious pruning these two books of 714 and 558 pages respectively have been brought together into a single work of about 500 pages. The special paper used makes the volume very light and pleasant to hold. It is to be regretted that the publishers are not consistent in their choice of type for paragraph headings, using generally small capitals, but occasionally, and for no obvious reason, heavy black-faced type. The first part gives a very thorough description of the various methods employed, the greatest stress being laid on the chronic intermittent treatment with mercury given by the mouth, because, as Fournier insists, treatment must be kept up for at least two or three years, because the drug must not be allowed to lose its effect as a result of continuous administration, and because ingestion is efficient in the great majority of cases and is the only method which patients will consent to follow for so long a period. Chapters are devoted to inunctions, injections, and the use of potassium iodide, the value of all being fully recognized. The second part treats of the prophylaxis of syphilis by State regulation, by protection of nurses, by treatment, and by instruction, and is remarkable chiefly for the overwhelming evidence it affords of the havoc wrought by this disease among those who suffer from it through no fault of their own, recalling in this section the excellent treatise on "Syphilis Insontium," by Bulkley, of this city.

Diseases of the Stomach. A Textbook for Practitioners and Students. By Max Einhorn, M.D., Professor of Clinical Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Hospital. Fourth Revised Edition. New York: William Wood & Co., 1906.

Dr. Einhorn's book is already so well and so favorably known to the profession that its appearance in a new edition does not demand detailed discussion. Gastric ailments have always been and will always continue to be among the commonest disorders that the practitioner encounters, but their successful management is often a matter of the greatest difficulty. The present volume was designed to assist in coping with the problems these cases involve, and it is extremely practical in conception and execution. The chief considerations of pathology and etiology are given due weight, but the greatest merit of the work lies in the clear and detailed expositions of the methods of diagnosis and treatment. The author's many contributions to this field have met with general appreciation, and in his textbook he presents in concise and readable form the results of his wide experience in special practice. Among the more important additions to this edition are profusely illustrated discussions of the application of the Roentgen rays and radium for purposes of gastric diagnosis. It is a pleasure to commend this highly serviceable book to the attention of all medical readers.

Traité d'Hygiène. Publié en Fascicules sous la Direction de MM. P. Brouardel, Professeur à la Faculté de Médecine de Paris, Membre de l'Institut; E. Monsy, Médecin de l'Hôpital Saint-Antoine; III Anthropologie, Hygiène Individuelle, Education Physique. Par R. Anthony, Secrétaire de la Société d'Anthropologie; E. Dupré, Agrégé à la Faculté de Médecine, Médecin des Hôpitaux de Paris; P. Ribierre, Ancien Interne des Hôpitaux de Paris; G. Brouardel, Médecin des Hôpitaux de Paris Auditeur au Conseil Supérieur d'Hygiène; M. Boulay, Ancien Interne des Hôpitaux de Paris; V. Morax, Ophthalmologiste des Hôpitaux de Paris; P. Lafeuille, Médecin-Major de l'Armée. Avec trente-huit figures dans le texte. Paris: J.-B. Baillière et Fils, 1906.

The present volume of this excellent series is attractively arranged in several sections, the first two of which are devoted to the consideration of physical and psychical anthropology, respectively. The means of studying the human form from life, including instruments and technique, and the use of statistics, are first considered. A discussion of the normal method of growth closes this section. Evolution and psychical growth are next taken up—phylogenesis and psychical ontogenesis, education of the intellect, physiological effects of fatigue of the mind, and the methods of estimating this fatigue in students and their practical applications follow in order. The remainder and greater part of the volume is given up to the consideration of Individual Hygiene in its different aspects. Under this subject clothing, its use, materials, various articles for different parts of the body and for the different ages, as well as cleanliness and disinfection of the same are all treated of in considerable detail. Following this is a most interesting chapter on the care of the skin, including the aspect and structure, the functions and microorganisms of this organ, as well as the subjects of baths and soap. The hygiene of the ear, nose, mouth, and throat, in both the infant and adult, is followed by a section on vision. The last part of the text treats of physical exercises and physical education. These subjects like the preceding are discussed in a broad and interesting manner. This work will prove a most valuable addition to any library.

Letters from a Surgeon of the Civil War. Compiled by Martha Derby Perry, Author of "God's Light as It Came to Me." Illustrated from Photographs. Boston: Little, Brown & Co., 1906.

These delightful letters were written by the late Dr. John G. Perry of Boston, who took part in the Civil War as a surgeon with the Army of the Potomac. While a student at Harvard he entered the army as a volunteer assistant to Dr. Cushing at Fortress Monroe in 1862. In April, 1862, he went back to Boston on account of a serious illness, and afterwards passed his graduating examinations. On March 18, 1863, he married the compiler of the letters. A month after his wedding he returned to the army with the Twentieth Massachusetts, taking part in the military operations at Fredericksburg, Falmouth, Culpepper, Bristoe Station, Mountain Run, Stevensburg, The Wilderness, and at the hospital near Petersburg. The letters were written to his sweetheart, later his young bride, during the campaigns and are alive with human and historic interest on every page. The book makes good reading for the doctor's family and for the waiting patient in his reception room.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held December 20, 1906.

THE PRESIDENT, DR. CHARLES L. DANA, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Surgery.

General Considerations in Reference to Blood Examination in Surgical Diseases.—Dr. FREDERIC E. SONDERN read this paper. He said that laboratory investigations, no matter how important, were an aid only to the clinician; they did not and were never intended to replace his clinical diagnostic skill or his prognostic ability based on clincal experience. Blood examinations in surgical cases were an aid in determining the general state of health before and after surgical procedure; they aided in the diagnosis of conditions inducing lesions subject to surgical intervention or those complicating surgical diseases or their convalescence; they furnished information in the differential diagnosis between some surgical disorders and lent aid in determining the degree of depletion due to hemorrhage; and finally they presented evidence of decided value in determining the presence or absence of an inflammatory lesion, and, in the former event, they might indicate the degree of toxic absorption and the resistance offered by the animal economy toward this infection. The arbitrary rule that no surgical procedure should be undertaken when the amount of hemoglobin was below 30 per cent., while better than no rule was crude in the light of present knowledge. The evidence in the blood of malaria, typhoid fever, the different forms of leukemia, Hodgkin's disease, and the different types of anemia were often of decided value to the surgeon not only in diagnosis but also in differential diagnosis. The value of blood work in the differential diagnosis between Hodgkin's disease and sarcoma and between secondary anemia and so-called pernicious anemia needed no comment. The determination of the coagulability of the blood was of value to the surgeon particularly as means had been devised for increasing the coagulability prior to the operation. The determination of the opsonic index would lack practical application until ways and means were found for increasing this index when desirable. The most important service the blood examination could render the surgeon was to give information regarding the presence or absence of an inflammatory lesion, some idea of its severity, and some indication of the resistance offered. Iodophilia as a guide in this regard had not rendered signal service in his hands. Since advocating the value of the differential leucocyte count as an aid in the diagnosis of acute inflammatory lesions and the added significance it gave to the leucocytosis, his daily contact with cases in which this diagnostic help was sought strengthened his belief in this adjunct. In the application of this procedure it was absolutely necessary to keep in mind the fundamental principle on which it was based: the increase in the relative number of polynuclear cells was an indication to the severity of the toxic absorption, and the degree of leucocytosis as evidence of the body resistance toward this absorption. As in every other technical procedure, the differential count to be at all accurate demanded proper technique and faithful execution, usually expected but by no means invariably obtained from the hospital interne and even from the pathologist's assistant, as he had reason to know from control examinations which he had been asked to make. This diagnostic procedure lacked many refinements, and he added a few words concerning the disappointments and failures sometimes encountered. Children, and particularly infants, did not give the uniform results obtained in adults; in these the normal polynuclear percentage was a more variable quantity. When a purulent exudate was confined in dense pyogenic membrane so that no toxic absorption occurred, or when a purulent exudate was the result of a tuberculous or typhoid infection alone, there was no leucocytosis and no polynuclear increase. Suppurative bone lesions, and particularly suppurative processes on the surface of mucous membranes, showed lower counts probably on account of slower toxic absorption. Mixed infections, with or following tubercle bacilli or typhoid bacilli, did not show the extreme polynuclear percentages noted in primary staphylococcus and particularly streptococcus infections. The exact nature of the infection also had a bearing on the degree of polynuclear increase, some organisms causing higher percentages than others, everything else being equal. In closing he said that it was unfortunate that this diagnostic aid, blood cultures in septic conditions, had not found more favor in private practice.

The Surgical Application of Blood Examinations.—Dr. JOHN B. DEAVER of Philadelphia presented this paper. He considered what proper estimate might be placed by the surgeon upon the results of blood examination. These examinations in acute posthemorrhagic anemias were of more value after operation in indicating the rapidity with which the blood returned to normal. In these cases it was extremely common that the red corpuscles were restored sooner than the hemoglobin percentage. He said that diagnostically he had found the number and character of the red cells and the percentage of hemoglobin so nearly similar in patients afflicted with chronic suppurative processes and in others with malignant tumors, as *per se* to be often of no value. Given a hemoglobin percentage below 25, a paucity of small distorted red blood-cells and a disease-spoiled body, he considered the patient's condition provocative of the surgeon's most serious and sober contemplation. To him the white blood-cells had been a frequent source of perplexity. Clinically, one usually followed this biological phenomenon by comparing the number of leucocytes to the condition in which the patient was found shortly after the count was made, or, later, by comparing these various counts to each other and to the course of the disease, so that in this manner one should have a reliable indication of the presence of inflammation and suppuration, and should be able to gauge its course and severity. Now and then a case occurred in which a bacterial invasion did not permit itself to be revealed by any such method, and so he had been compelled to employ such terms as "usually" and "should have." If he had been asked to explain the *modus operandi* in those negative cases he said that he might reply in such indefinite phrases as "lack of resistance," "personal susceptibility," "impaired state of health," "idiosyncrasy," and so on, but instead he would resort to the subterfuge of answering a question by a question, and ask for example, why, in the Jewish race, diabetes mellitus was so frequently encountered, and tuberculosis so seldom, or why the Japanese were so immune to scarlatina, and the negroes to malaria? Therefore, with these reservations, leucocytosis would usually be found in infections leading to suppuration in any part of the body. In appendical abscess a leucocytosis was the rule, and, in looking over his records for the last 100 cases, he found that the count varied from 6,300 to 47,200, with an average of 17,760. Those below 10,000 numbered 10; between 10,000 and 20,000 numbered 61; between 20,000 and 30,000 numbered 23; above 30,000 numbered 6. The diagnosis of appendicitis was most frequently confused with pyosalpingitis and with biliary tract disease and a comparison of the counts was therefore of interest. In appendicitis with abscess (extra-appendical exudate) the high was 47,200; low, 6,300; average, 17,760; above 10,000, 90 per cent.; above 15,000, 62 per cent. In pyosalpingitis, high, 42,200; low, 5,300; average, 13,000; above 10,000, 67 per cent.; above 15,000, 32 per cent. In biliary tract disease, high, 23,300; low, 4,000; average, 0,000; above 10,000, 15 per cent.; above 15,000, 6 per cent. Dr. Deaver believed that iodophilia was of little value. It was only of value in the detection

of suspected deep abscesses when the leucocyte count had proved normal. In gall-bladder cases associated with jaundice he had found the time of coagulation had been delayed. Dr. Deaver believed that the greatest value of the differential leucocyte count was obtained by the general practitioner, if he had the requisite training for the work and the time; but he asked how many men were able in a suspected case to take the blood, go back to the office, spend twenty minutes on the white cells, stain the films, and count at least 500 leucocytes. This was practically impossible.

The Clinical Value of the Differential Blood Count in Operative Otology.—Dr. James F. McKernon asked if a differential blood count would help in doubtful cases to make a more accurate diagnosis. He thought it would, and this opinion was based upon the differential leucocyte count in 166 operative cases, 108 of which were adults and the remaining 58 being children ranging in age from six months to twelve years. In all of these the differential leucocyte count was taken as an aid in diagnosticating mastoid disease, and the sequelæ resulting from it. Of the 108 adult cases, a positive diagnosis of mastoid involvement was made in 84 without recourse to the blood count, which was made only for confirmatory evidence. Of this number of cases the lowest polymorphonuclear percentage was 73.2 per cent., the highest 97.6 per cent. In the 24 remaining cases many of the typical symptoms of the disease were absent, and it was here that the differential leucocyte count proved of the utmost value. Of these 24 18 did not present the usual clinical signs of mastoid disease, and it was only after a differential leucocyte count had been made that an operation was decided upon. Of these 18 cases the lowest polymorphonuclear percentage was 73.2 per cent., the highest 86.4 per cent., and all contained pus in the mastoid. The remaining six cases were complicated with a phlebitis of the sigmoid sinus, and in these cases the polynuclear percentage prior to operation was high, the highest being 96.6 per cent., and the lowest 86.8 per cent. Of the 58 cases in children a positive diagnosis of mastoid involvement was made in 47 prior to the differential count. The lowest polynuclear percentage was 68.6 per cent., the highest 82.8 per cent. Of the 11 remaining cases none exhibited the usual symptoms of the disease, and here again the differential leucocyte count proved of value in 8 cases. Of these 8 cases the lowest polynuclear percentage was 72.2 per cent., and the highest 83.4 per cent., and pus was found in abundance in the mastoid process. In the 3 remaining cases there was nothing to explain the high temperature, and marked prostration, except the presence of a discharge from the ear. The lowest polynuclear percentage was 42.4 per cent. and the highest 56.8 per cent., and from this the natural deduction would be absence of sepsis, but in relation to this low polynuclear percentage was a marked decrease in the number of white cells usually found. Upon operation an abundance of pus was found in each of these three cases. The conclusions he arrived at were that in septic cases the differential blood count was of practical value in enabling one to complete a diagnosis: in cases of sepsis, when the physical symptoms and signs are distinct and definite, it was then only confirmatory and gave an added link to complete the chain of evidence. A fact of importance brought out in this series of cases was that when cellular bone structures, like the mastoid, were involved in a septic inflammation, without involvement of the adjacent blood currents, one found that in the majority of the cases the differential count showed a relatively lower polynuclear percentage than when a septic process was present in the soft tissues of the body. This could be explained on the theory that an absorption of toxins was less rapid when such a process took place in a bone cavity. A point mentioned by Dr. Sondern, and corroborated by a study of the above cases, showed that when there was a pronounced leucocytosis and a pronounced polynuclear increase it was indicative of a severe infection with good systemic resistance, and that a pronounced polynuclear increase with little or no leucocytosis showed a severe grade of infection, with but little body resistance, and also that the increased polynuclear percentage, with stationary or decreasing leucocytosis, showed an increasing degree of infection, with decrease of body resistance.

The Value of Differential Leucocyte Counts in Gynecology.—Dr. Howard Canning Taylor read this paper, dividing it into the consideration of three sections, as follows: (1) Ectopic pregnancy. In this the blood count was that of hemorrhage from any cause. The amount of leucocytosis depended upon the amount and rapidity of the hemorrhage, reached its highest point within a few hours, and diminished rapidly during the following three or four days, reaching normal only after a number of days more. With a recent hemorrhage the high total count and high percentage of polynuclear cells, taken with an absence of temperature, were signs that rarely would point to any other condition. (2) New growths. If uncomplicated he had found no change in the leucocyte count. If the new growth, for instance, a fibroid tumor, became infected, or if there had been a recent degenerative change or a hemorrhage sufficiently extensive to produce a posthemorrhagic leucocytosis, one found change in the leucocyte count. With carcinoma, either of the cervi or fundus of the uterus, any leucocytosis that might be present was due to the complicating inflammation and not to the growth itself. (3) Inflammatory diseases. The most marked changes in the blood count were found in inflammatory diseases of the appendages. In an acute case both the total count and the polynuclear cells were increased in proportion to the severity of the disease, decreasing as the condition improved. If the infection was tubercular there was usually little or no change in the count. In gonorrheal infections the changes were less marked than in more severe forms of infection. He emphasized the fact that blood counts should be considered with the other symptoms, and to be of the greatest value there must be repeated counts. The negative condition of the blood that was found in uncomplicated new growths was not of the same value as the positive findings of the hemorrhage following ectopic pregnancy, or of the inflammatory diseases, yet it was of value in excluding other conditions that might be present as complications. In the inflammatory diseases the blood changes were more marked and more constant. There was, beyond doubt, a definite relation between the amount and the virulence of the infection and the blood changes.

Dr. Howard Lilienthal believed that in the matter of blood examinations there was other than the leucocyte count, and that something would have to be done to have more frequent examinations made by the chemist, and less by the microscope. Blood cultures were of enormous importance in prognosis in serious peripheral disease. In acute abdominal cases these examinations were not so important because the bacteria were stopped by the viscera, particularly the liver, and any secondary invasion of the general blood stream did not come until long after the primary invasion of the liver. Blood cultures were very important in prophylaxis. In the acute infectious surgical diseases Dr Lilienthal said he had come to the conclusion that in determining whether to operate or not the blood count could be entirely disregarded. In every case that he waited for the blood findings he said he was sorry; but he had never been sorry when he went ahead and did not wait for blood counts. He reported three interesting cases. The first was a gentleman fifty years old, sent by a colleague because of a thick induration of the face, and which eventually developed into a malignant carbuncle of the lip. There was considerable swelling and brawny infiltration. Incision was at once made. No pus was present. The blood count was practically normal. Another operation became necessary two days later, when he tied the facial to prevent invasion of the circulation by sepsis. A blood culture taken from a vein of the foot gave positive

results. No pus was present at any time. The number of leucocytes was normal, the polynuclears were low, and prognosis bad. There was no enlargement of the lymph nodes. Operation was again resorted to, and the patient died. The second case was a fat woman who was suddenly stricken with severe right-sided abdominal pain, vomiting, and with temperature of 103°. Twenty-four hours later she was admitted to the hospital with these symptoms and with an irreducible umbilical hernia. There was a question as to the existence of a strangulated hernia with gangrene or appendicitis. The leucocytes numbered 30,000, the polynuclears 90 per cent. A small incision over the appendix was made and revealed the fact that she was suffering from a twisted ovarian cyst. The cyst was removed and the patient did well. He expected to find a suppurative process, but there was no pus anywhere. The third case was a boy of seven years with typhoid fever, who had a sudden drop in the temperature, but no increase in the pulse rate, no prostration nor other signs except distention, the latter not being present when the drop in temperature occurred. The blood count was normal for typhoid, *i.e.* leucocytes 7,000, polynuclears 67 per cent. He decided to wait three hours in order to see whether the blood count would go up. At the end of that time there was more distention and an exploratory incision was then made. A large perforation was found, peritonitis developed, and the boy died. Waiting for the leucocytosis lost him two, three, or four hours.

Dr. Nathaniel B. Potter spoke of the difficulty of estimating the value of the differential count in children. Again in the City Hospital where they had so many chronic cases the differential count was very irregular, and they never had been able to follow any rule. In regard to the value of the hemoglobin estimation, he said he had found that even with a low percentage these patients stood operations fairly well; whereas, if there was a sudden drop in the hemoglobin percentage and a low count, they would not stand operations as well. The determination of the opsonic index was a very complicated problem, and he did not believe it would be of any practical value until the technique was simplified. It could be stated, though, that, in a large percentage of chronic localized staphylococcus infections, and in some cases of chronic localized tuberculous infections, raising the opsonic index by proper doses of dead cultures of the corresponding germ would improve the patients materially, if not cure them. He told of the observations made by himself and coworkers last summer in cases of appendicitis. He believed that the future for infections like chronic acne, or general furunculosis, carbuncles, sycosis, and in some of the other staphylococcic infections, was very bright for the use of this method of treatment. It was too soon to say what the future would be for tuberculosis. The great trouble at present was the difficulty encountered in making a uniform emulsion of the tubercle bacilli which would phagocyte with regularity. Dr. Trudeau's experiments with tuberculin led one to believe that if they could determine the tuberculoopsonic index they might eventually cure more cases which hitherto had been helpd but little.

Dr. George Sloan Dixon thought they all would agree with what had already been stated, that the examination of the blood was simply an aid in diagnosis. In diseases of the ear the leucocyte count was likely to be low because, the disease being in the bone, did not affect the circulation as though in the soft parts. He showed some charts which were based on some selected cases. There were 51 cases of purulent chronic otitis media, with or without complications, and 77 cases of acute purulent otitis, with or without complications. The blood counts were made only at or about the time operation was performed. In the acute cases the leucocytosis rose from 9,000 to 17,500 without complications; those that were complicated with mastoiditis ran a little higher. The polynuclear percentage in the acute purulent otitis media cases ran from 40 per cent. to as high as 81 per cent., and much the same curve was shown in the mastoiditis cases. The most important feature was that when the patient had a sudden rise in temperature with a leucocytosis running as high as 25,000 or over, whether a high polynuclear percentage or not, they were likely to find a pneumonia or meningitis present. If 20,000, it was noted that a meningitis would develop within twenty-four hours; if beyond 25,000, probably a deep pneumonia. In the chronic cases the curve was a trifle lower, and the same held good for pneumonia and meningitis. The highest percentage of polynuclears in meningitis noted was 97 per cent.

Dr. Max Einhorn said that twenty-two years ago he undertook to study the relation of the lymphocytes to the blood corpuscles and made differential counts in normal and diseased individuals. This claim was upheld by the presentation of some of his writings on the subject at that time.

Dr. Samuel Lloyd emphasized the necessity of a complete blood count, and that we should not depend upon a partial one. He believed, too, that there was something in the idea advanced lately regarding lymphocytosis in progressive septic diseases. One should not depend upon the percentage of polynuclears alone, but should take them down the scale, noting any increase in the other blood elements which might give an indication as to the progress of the disease. With regard to the hemoglobin percentage as an index for operative work, the rule of 30 per cent. he believed to be too high; he said he had operated successfully in cases where the percentage of hemoglobin was 20 per cent. Much was yet to be studied on the coagulability of the blood, and it was particularly of value in cases of long-standing jaundice where one anticipated a dangerous hemorrhage. Dr. Lloyd said he had had one case in which the coagulability was thirteen minutes. He referred to Dr. Crile's suggestion that where one got a reduced hemoglobin, or a preoperative anemia, or where other conditions were present which reduced the hemoglobin too low, direct transfusion of blood could be done and often with marked success.

SECTION ON MEDICINE.

Stated Meeting, Held December 18, 1906.

Dr. Warren Coleman, Chairman.

A Case of Aneurysm.—Dr. William B. Noyes reported this case at the request of Dr. Lewis and Dr. Keller of the Columbus Hospital. The previous history was practically negative except that the patient had syphilis fifteen years ago, and used alcohol in excess. Seven days prior to admission the patient suffered from cough and expectoration, the sputa being bloody. Physical examination showed the patient to be fairly well nourished. The apex beat was not localized by inspection, the greatest point of intensity being over the fourth costal cartilage, one inch to the right of the sternum. Area of impulse extended all over the chest wall. The first sound was diffused over the anterior chest of greatest intensity to the right of the sternum. The second sound was accentuated and the respiratory murmur was absent on the left side. The vocal resonance was decreased over that side and hyperresonant over the right chest. Examination of sputa was negative as to tubercle bacilli. The voice of the patient was noticeably hoarse. On November 26 a needle was introduced posteriorly and four ounces of fluid was aspirated; this had a specific gravity of 1.010, was alkaline in reaction, reddish in color, and coagulated, but not spontaneously. It contained large numbers of red blood-cells. Two days later laryngoscopical examination showed that the left vocal cord was paralyzed. At about this time tracheal tug was obvious. On November 29 a systolic murmur, low pitched with greatest intensity over the internal half of the clavicle, was noted. There was no temperature, and the patient was up and about the

ward. He expectorated bloody fluid and sometimes pure blood. He died suddenly December 12, 1906. At autopsy the right pleural cavity was found to be free of adhesions, but the left pleural cavity was obliterated by dense adhesions, laterally and posteriorly. The left lung was compressed and hard to identify, being replaced by a mass consisting of clots of blood, some recent, red, or black, some appearing of long duration. The heart was flabby, dilated, while the tricuspid and mitral valves were normal. The aorta showed very great atheromatous changes and was constricted above the semilunar valves. At the transverse arch of aorta and upper part of descending aorta was an aneurysmal sac the size of a cocoanut, and which had ruptured into the posterior mediastinum. The walls were thick, except over the rupture, which was very thin. The diagnosis was made of aneurysm even before the tracheal tugging was noted. The aspirating needle was thrust through the aneurysm. From the syphilitic history given the probabilities were that this was a syphilitic process and not due to ordinary atheromatous changes.

Dr. Charles H. Lewis said that the case was of interest from the presence, as well as the absence, of certain clinical signs and symptoms. In the first place, the complete flatness over the upper left side, due, as shown at the autopsy, to the entire absence of lung tissue; then the tracheal tugging was well brought out. These signs, together with the paralysis of the left vocal cord, and the strong aortic second sound, were the ones on which a diagnosis of aneurysm was based. There was no expansile or heaving pulsation over the flat area, no bruit was heard, and no difference in volume or time between the right and left pulse was detected, although carefully and repeatedly looked for. Dr. Lewis said that he had introduced a small exploring needle about one inch below the spine of the scapula and withdrew a hypodermic syringeful of what he then supposed to be serosanguinolent fluid. He thought this fluid was in the pleural cavity and secondary to the aneurysm. He directed the house surgeon to aspirate in the same place, which was done a few days later, and "the four ounces withdrawn" was reported by Dr. Noyes. Dr. Lewis had grave doubts as to whether the fluid came from the aneurysmal sac, which presumably would contain pure blood. One could, however, perforate such a sac with a small needle without the slightest harm. This he had done in other cases and he had withdrawn blood in order to differentiate aneurysm from solid tumors. In this case the rupture occurred at some distance from what was supposed to be the tract of the aspirating needle.

Dr. Noyes said that the left pleural cavity was almost completely obliterated with adhesions and the right pleural cavity was practically normal. The left lung was practically cornified from pressure from the aneurysm and from the clots. The aneurysm had been leaking before the final rupture if the old clots and the ragged state of the lining membrane of the aorta were any proof. How long this had been going on was hard to say. The patient seemed fairly well until the day he died. Histological examination of sections of the aorta had not yet been made, but on gross examination it seemed like a chronic inflammation, with a ragged, sloughy surface of a rather unusual pale-red color rather than the typical appearance of atheroma of the aorta. It seemed to him a chronic aortitis of a distinctly syphilitic nature.

Pathology and Symptomatology of Chronic Adhesive Pericarditis.—Dr. Montgomery Hunt Sicard read this paper. He said that among 2,000 autopsies at the Presbyterian Hospital there were 77 cases of fibrous pericarditis, or about 3½ per cent. of the post-mortem examination; 45 of these 77 were extensive, involving the greater part of the sac; 32 were slight; there was but one case of mediastinopericarditis. In 33 of these 77 there was existing endocarditis; in 5 gross myocardial changes occurred; in 15 there was marked sclerosis of the coronary arteries; in 4 severe aortic sclerosis; in 4 aneurysm, and in 33 chronic diffuse nephritis. Of these 77 cases 9 were tuberculous, 4 having pulmonary tuberculosis and 5 having general miliary tuberculosis. Among the 2,000 autopsies there were 329 cases of chronic endocarditis, so that chronic pericarditis formed about 5 per cent. of the cases of chronic valvular disease. At St. Mary's Free Hospital for Children, out of 97 autopsies there were 5 cases of adherent pericardium; there were also among this number 4 cases of pyopericardium with considerable thickening, but without actual adhesions. Symptomatically he divided the disease into a number of fairly well defined classes. (1) Cases that ran a latent course and were only discovered upon the autopsy table; (2) those cases in which one, during a routine examination, discovered a harsh systolic murmur over the pulmonary area, increased by pressure and by leaning forward, the pulmonic second sound being accentuated; (3) cases with circulatory embarrassment, palpitation, irregularity, and intermission of heart beats, sometimes precordial pain, with moderate general hypertrophy, and sometimes tenderness over the base of the heart. No murmur or friction sound was heard to account for the cardiac change and so only a tentative diagnosis was made from the absence of direct signs; (4) cases with adhesions between the outer surface of the pericardium and the neighboring structures; here there would be considerable enlargement of the heart with diffuse pulsation of the precordium and systolic retraction of the apex. The heart was pretty well fixed by adhesions; paradoxical pulse might be present; (5) severe cases of mediastinopericarditis resembling the last group except that the mediastinal inflammation was more widespread, with consequently more serious changes in the abdominal viscera. These patients suffered from cyanosis and dyspnea, and constantly recurring ascites. A curious appearance was the frosted or iced liver, "Zuckergussleber," a white, fibrous, thick mass of connective tissue coating the liver and leading to much irregularity and distortion. The picture in this last group of cases was enlargement of the liver and ascites, and it was difficult to differentiate it from cirrhosis of the liver. The chief factors of distinction were absence of the causes of cirrhosis, nondilatation of the superficial veins, absence of the common symptoms of liver obstruction as hematemesis, jaundice, hemorrhoids, diarrhea, or constipation, signs of chronic pericarditis. In mild cases patients died of intercurrent disease which had nothing to do with the pericarditis. In severe cases there was a gradual cardiac failure due to increasing dilatation. Sudden death might occur at any time from myocardial degeneration or coronary sclerosis.

Dr. C. N. B. Camac referred to the Broadbent sign, and said there were great variations in the signs of adherent pericarditis, much like the signs of endocarditis, and they depended upon how much of the pericardium was involved and also what part of it. As the pericardium was possibly attached to the deep cervical fascia and below to the lateral wing of the diaphragm, perhaps to the central tendon, he said it was a question whether they could get Broadbent's sign if the pericarditis involved that portion in contact with the diaphragm. He said he had in mind three cases, two of which came to autopsy. Broadbent's sign was present, but disappeared. This was a very important sign in making a differential diagnosis, especially in differentiating pericarditis from those painful affections at the base of the heart. Broadbent's sign with the pulse under the ensiform he believed to be pathognomonic of adherent pericardium. Another point was the bulging of the precordium; this was not necessarily a sign of enlargement of the heart, or enlarged and adherent heart. He did not know what statistics gave regarding ascites with adherent pericardium. In two cases reported by Osler there was a definite perihepatitis and a perisplenitis; in both cases during life the diagnosis was simply that of congestion of the liver. Much confusion existed regarding cardiac murmurs. In both of the cases mentioned there were no valve lesions at all, and yet there was a distinct diastolic and systolic murmur. The interpretation of murmurs in adherent pericarditis was extremely difficult as it was in endocarditis.

Dr. Theodore C. Janeway took exception to Dr. Sicard's

statement regarding the murmur over the pulmonary area which he said was intensified by leaning forward; it seemed to Dr. Janeway that this harsh pulmonary murmur was frequent in perfectly healthy men, and he had observed many such in West Point students, and among the most competent athletes in the class. Among these men there would even be noted a thrill when they leaned forward. In these cases the murmur would disappear on full inspiration.

Dr. Theo. B. Barringer said he had seen four cases of supposed adherent pericardium, three of which came to autopsy. In the first case there was no retraction of the precordium; only a rapid heart, congestion of the liver, some ascites, moderate cyanosis, and edema. The diagnosis was made of myocarditis. At autopsy adhesions of the pericardium were found. In this case there were no murmurs; the only physical signs were those showing insufficiency of the right ventricle. In the second case there was a systolic retraction of the precordium, Broadbent's sign, and disappearance of the apex beat. At autopsy the external layer of the pericardium was found to be adherent to the pleura and liver. In the third case there was systolic retraction of the precordium, Broadbent's sign, and a loud systolic murmur. At autopsy there was found a stenosis of the pulmonary valve, an hypertrophied right heart, but no adherent pericardium. The last case did not come to autopsy, but the boy, aged fifteen years, had all the classical signs of adherent pericardium. He thought that those cases where the internal and external layers of the pericardium grow together were the easiest to diagnose.

Dr. Sicard said that at Cornell University during eighteen months he had a number of cases from which he drew his conclusions. Murmurs were present all the time and were exceedingly harsh and grating. One should bear in mind the chances of congenital heart lesions; these would frequently be found in a routine examination, and would not cause any trouble during life.

Specimen of Chronic Bacterial Endocarditis, with Remarks.—Dr. E. Libman believed in calling all endocarditis cases acute, subacute, or chronic, according to the duration. If bacteria were found in the blood one could add the name of the infecting organisms. The cases of chronic and subacute bacterial endocarditis have been called ulcerative endocarditis, malignant endocarditis, etc., but such terms had not been found satisfactory. Among the cases of subacute and chronic endocarditis in which the heart valves were attacked by bacteria, one of two types of organisms was usually found, either a streptococcus which grew poorly or an organism which looked like the pneumococcus, but which had no capsule and which otherwise could be differentiated. These organisms had not been isolated. Dr. Libman reported as an example the case of a woman twenty-seven years old whom he saw June 11, 1906. She had had rheumatic attacks in the joints of her lower extremities for six weeks and had been bedridden three times. She never had tonsillitis. One year before admission to the hospital she had dyspnea and cardiac palpitation. She had pains in different parts of the body, but particularly in the joints of the lower extremities. She coughed and sweat at night. When examined on admission there were petechial spots on the abdomen and the dorsum of both hands. There were evidences of enlargement of the right heart. At the apex there was heard the snap of a mitral stenosis. A presystolic murmur could not then be heard. The liver was enlarged, but the spleen was not palpable. There were thrombosed veins in the leg and a periphlebitis. During her stay in the hospital the temperature was exceedingly irregular. Sometimes it was 101°, and again it would be 103° or 104°. On June 16 pain in the region of the spleen was noted, and this organ could be felt below the free border of the ribs. On June 19 pain in the thyroid cartilege was complained of. Examination of the blood was interesting. There was no increase in the leucocytes; these numbered about 8,400, sometimes as low as 5,600. The polymorphonuclears ran from 72 per cent. to 80 per cent. The hemoglobin was 80 per cent. and diminished to 45 per cent. There developed tenderness over the sternum and over the tibiæ. June 30 she complained of pain in the right lumbar region. The kidney was found to be distinctly enlarged, tender, and red blood-cells were found in the urine, probably from an infarct of the kidney. July 18 no changes were found in the retina. August 28 the right knee joint became swollen, reddened, hot, and tender, persisted for several days, and then subsided. There were signs of infarct of the right lower lobe, increasing temperature, gradual failing, and she died September 20. The urine contained albumin, casts, and red blood cells. In each of the five blood-cultures taken an attenuated streptococcus was found. There were about twenty to the cubic centimeter of blood. The organism was not virulent, even for mice. At autopsy vegetations of a greenish color were found on the mitral valve; they extended into the auricle. Many infarcts were found in the lungs; the plugs were not as ordinarily found, but distinctly yellowish; some were rather soft, but there was no pus in the thrombi. There was an open foramen ovale. The infarcts were produced by transmission of these plugs from the mitral valve, through the open foramen ovale, and so to the lungs. At the hospital they had had fourteen or fifteen cases and all had come to post-mortem except two. In many of these cases there was a mitral stenosis, but a presystolic murmur could often not be heard, especially when there was fever. These cases should be carefully watched until the fever subsided. Petechiæ were found as a rule practically in all the cases, and they were very suggestive, especially when the diagnosis was not clear. Dr. Libman asked what the temperature was due to. His own impression was that the sharp rise was due to the discharge of emboli from the heart valve, and their lodgment somewhere. As a rule the leucocyte count was 13,000 or less. The progressive anemia was curious and not easily explained, but was probably due to hemolysis. In the case reported the bacteria lodged in the arteries of the spleen, causing an infarct; they grew along the vessels and extended to other vessels. In all these cases of endocarditis extending along weeks or months these two organisms would be found constantly; if one got one of these organisms from the blood he could be certain that he was dealing with an acute infection of the heart valve. With regard to the relation of these cases to rheumatism he could not claim that rheumatism ever had anything to do with them. All one could say was that there was a tendency to infect a valve that had previously been damaged by rheumatism.

Dr. Alfred Meyer said that in looking for confirmatory evidence, if petechiæ could not be found in the skin they might be found in the conjunctiva, and in quite a number of cases in the mouth. With regard to the treatment of this disease, he believed in the use of silver salts. In ulcerative endocarditis or bacterial endocarditis of chronic type he used an ointment of colloidal silver, applying half a dram twice a day, and rubbing in for twenty minutes in order to insure absorption. Whatever had appeared in the discussion in reference to pericardial adhesions and the bacterial type of infections of the pericardium only confirmed the suspicion that auscultatory evidences were very deceptive and treacherous to deal with. In order to show how deceptive auscultatory evidences were he cited a case seen at Mt. Sinai Hospital, one of chronic endocarditis, with typical evidences of aortic insufficiency, capillary pulse, diastolic murmur in the vessels of the neck, and murmur over the pulmonic area, etc. In a few days the murmur was not audible anywhere. Later it returned.

Dr. Warren Coleman said that he had been using the silver salts in the treatment of infectious diseases for some years, but instead of ointment he used it intravenously in 1 per cent. solution, and sometimes he gave it per rectum.

During the summer he treated a case of infective endocarditis where several blood cultures failed to give results. He used silver twice a day per rectum, giving two or three grains, and the patient got well. He was not willing to draw any conclusions from this case, however.

Dr. Leonard Weber said he used ointment of silver in 40 per cent. or 50 per cent. strength. In two cases of severe puerperal septicemia, as acute as he had ever seen, one-half dram every three hours was rubbed in night and day. One of these women had a temperature of 100° and over. These cases recovered. Three years ago he saw a case that became acutely septic, a case of typhoid fever, and the results from this ointment were equally satisfactory. In other cases he had had good success with the ointment. But in a case of sepsis during the course of an attack of erysipelas involving the head, neck, and face it failed to show any influence whatever.

Dr. E. Libman closed the discussion.

The Prognosis of Cases of Transient Spontaneous Glycosuria and the Relation Between This Form and Alimentary Glycosuria.—Dr. Theo. B. Barringer, Jr., and Dr. Joseph C. Roper presented this communication, which was read by Dr. Barringer. They gave the following summary: (1) At the end of five years 20 per cent. of a group of twenty cases of spontaneous glycosuria had become diabetic, 15 per cent. had become suspicious cases, and 10 per cent. somewhat suspicious; 55 per cent. had remained free from diabetes. (2) Eight out of eleven cases of spontaneous glycosuria, in which sugar recurred, became diabetic or probably diabetic. (3) The alimentary glycosuria arising from glucose or cane sugar, provided the test was properly conducted and repeated at intervals, afforded a valuable aid to prognosis in cases of spontaneous glycosuria. A positive test was of much more value than a negative test. (4) Alimentary glycosuria following the ingestion of sugar was essentially diabetic in nature. They found that at the end of five years but 45 per cent. at the most of their cases had become diabetic. If it was possible, as they believed, to detect these cases at a relatively early date it would not seem necessary to maintain a permanently restricted diet in *all* cases. If a small quantity of sugar was found in a patient's urine, and there was no history of overindulgence in sweets, he should be placed on a restricted diet and the reaction to the glucose test should be frequently ascertained during the next six months. If the reaction were positive the restricted diet should be continued, even though the spontaneous glycosuria had not recurred. If the reactions were negative and sugar did not reappear a restricted diet would seem superfluous. The conflicting opinions as to the essential nature and diagnostic worth of alimentary glycosuria might be harmonized by more observation of the course of cases of spontaneous glycosuria and by the frequent determination of their reaction to the glucose test.

Dr. Theodore C. Janeway said that the paper showed the type of work which was of real value on a subject about which there was too much speculation. He reported one patient whom he saw in 1900 who had a transient glycosuria with catarrhal jaundice; after lasting two weeks it cleared up. This was followed by a diminution in sugar tolerance. After his jaundice the patient went South, but took along his test solution. While there he ate syrups, etc., but without any reduction of the Fehling's solution. For four years he never had sugar in his urine. He then developed a severe attack of pyonephritis with a reappearance of sugar in his urine, and since then he had been mildly diabetic with a slight tendency to loss of tolerance. He was never able to take bread, but could take an equivalent of eight ounces of bread. The possibility must be borne in mind that cases of spontaneous glycosuria might develop diabetes under certain circumstances, and it was incumbent upon them to pay attention to transient glycosuria and keep such patients under observation for a certain time. Dr. Janeway also called attention to the necessity of following children of diabetics and testing their glucose tolerance.

Dr. Theodore Stewart Hart said that the results obtained were particularly interesting because they were able to get results on patients under observation fifteen years. In studying the cases one must divide and classify the cases of diabetes and glycosuria. Testing with carbohydrates was interesting, especially in cases of glycosuria due to, or coincident with, liver lesions.

Dr. John J. Morrissey said that from the standpoint of a medical examiner for life insurance it should be borne in mind that glycosuria as a basis for statistical calculation, and glycosuria as a fundamental principle upon which to make a diagnosis of diabetes, were different. Glycosuria in itself was the red flag of danger; but he would not say that the majority of cases of glycosuria terminated in diabetes. One could get the slightest trace of sugar one or two hours after a hearty meal. Too much stress should not be placed on statistics.

Dr. J. Finley Bell said that in 1901 he had a case that was supposed to have transient glycosuria. Examination of the urine on a number of occasions was made and copper was reduced each time. Being desirous of having a quantitative analysis made, the fermentative test was applied with negative results. The urine would reduce Fehling's solution, but not bismuth. A few years ago he examined a patient for life insurance. The home office told him the patient had been examined by another examiner who found sugar in large quantities. He made further examinations, two being positive and one negative. He then learned that the individual had brought the urine in a bottle which had in it a piece of cork and syrup of figs.

Dr. Theo. B. Barringer, Jr., closed the discussion. He said that as the cases numbered only twenty only tentative deductions could be made.

Election of Officers.—*Chairman*, Dr. Warren Coleman; *Secretary*, Dr. H. S. Carter.

Chicago Medical Society.

At a regular meeting, held December 12, 1906, there was a symposium on "Exophthalmic Goiter." Dr. Frank Billings described the chief symptoms of exophthalmic goiter. He said he had records of sixty-one patients who had come under his direct personal care; eight were males and fifty-three females. Of the males two were acute, and the rest under chronic forms of the disease. One male had suffered from goiter for several years preceding the onset of the symptoms, and with seven the goiter developed as an incident of Graves' disease. Of the females thirty-two had no goiter preceding the development of the disease, while twenty had suffered from goiter for from three to twenty years. Ten of the fifty-three females suffered from acute Graves' disease, and in all of these acute cases the goiter was primary, that is, developed as a part of the disease. Thyroidectin was used in twelve cases. The powder form of the serum was used in a dose of from fifteen to forty grains a day in divided doses, with varying results. In no instance had he secured the favorable results recorded by many other physicians. In two instances the symptoms were aggravated by the remedy. He had used the hydrobromate of quinine in eight cases. This drug had been given in from fifteen to thirty grains in divided doses in twenty-four hours. It had afforded a more uniform improvement in the symptoms due to vasomotor disturbances than any other drug. He had used the serum of thyroidectomized goats prepared under the direction of Moebius, in one male. This patient was put upon rest treatment in the hospital, and in addition to the full doses of the serum hydrobromate of quinine was given. The improvement was steady and continuous. He had not had experience with the use of specific serum prepared by Beebe of New York, and used by Rogers and Thompson in the treatment of thirty-nine or more cases. Three

of the patients included in the group were operated on, and of this number two made satisfactory recoveries and have remained well, while one died on the operating table. Dr. Dean D. Lewis discussed the pathology of exophthalmic goiter. Dr. R. B. Preble spoke of the cardiac symptons. Dr. L. Harrison Mettler suggested three principles that he believed would be found useful in distinguishing the presence of any of the said diseases in a patient who might at the same time have exophthalmic goiter. The first principle was to keep close to the narrow definition of Graves' disease as being represented in one or more only of the cardinal symptoms—tachycardia, struma, exophthalmos, no matter what the other neurasthenic, hysteroid or general nervous manifestations might be. Whether regarded as a mere syndrome, or as the essential expression of the disease, the famous triad in part or in whole must be the basis of diagnosis and nothing else. The second principle was that we should always endeavor to align the so-called secondary, nervous symptoms of exophthalmic goiter with any other corresponding symptoms present that belong to some other distinct, well-known trouble. The third principle was that all organic diseases and all symptoms that represented an organic lesion were complications rather than a mere part of the exophthalmic goiter. Cardiac valvular lesions, tabes dorsalis, ocular palsy, multiple neuritis, for example, were complications and should not be confused with the symptomatology of Graves' disease. Dr. Casey A. Wood discussed the ocular signs and symptoms. Dr. William E. Quine spoke on the medical treatment of exophthalmic goiter, and under this head discussed rest, diet, hydrotherapy, electricity, the Roentgen ray, organotherapy, serum therapy, medicinal therapy, and saline purgatives. Speaking of serum therapy the author said that two kinds of serum had been introduced—the serum of thyroidectomized animals, and the serum of animals treated with increasing doses of thyroid extract. Neither of these products had furnished important results. In medicinal therapy iodine usually proved hurtful. The same was true of digitalis and strychnine. Belladonna, given in the dose of ten minims of the tincture, three or four times a day, was recommended by more writers than any other medicine; but to the author it seemed inferior to some others. Forchheimer recommended the employment of hydrobromate of quinine, given in the dose of five grains every six hours, sometimes alone, and sometimes with the addition of one grain of ergotin to each dose. Salicylate of sodium, in the dose of ten grains, repeated every six or four hours, usually subdued symptoms for a short time, but its effects were not lasting. Of saline purgatives, the phosphate and the glycerophosphate of sodium were of undoubted value. In his own practice improvement of the patient under their use had rarely failed to occur. Aside from the saline purgatives, the medicines he had learned to rely on most were [illegible], digitalis, and the bromides. Pulverized strophanthus in the dose of one grain, codeine one-third to one-half grain, and bromide of sodium in the dose of twenty grains, each repeated at regular intervals three or four times in twenty-four hours, often proved very serviceable. It was usual for him to give two of these medicines, but not codeine and the bromides at the same time. He estimated that 60 or 70 per cent of the cases of exophthalmic goiter terminated in recovery under medical treatment. Some cases terminated spontaneously in this way, and he had witnessed three instances in which the occurrence of pregnancy contributed to the result. Charcot had recorded a similar observation. When medical treatment had been well sustained for six months without distinct benefit to the patient, or if the patient should get worse under the best medical treatment that could be devised, surgical treatment must be considered. Dr. Arthur Dean Bevan reviewed the development of the surgery of the thyroid gland, and reported the results obtained in seventeen cases of exophthalmic goiter in which he operated. Two of these patients died, one on the table, and the other shortly after operation. Dr. Carl Beck demonstrated two rare cases. The first was a case of "Suppurative Thrombophlebitis of the Iliac Vein," following a primary infection of a finger. There was general pyemia, with many localizations, but one very extensive thrombosis of the femoral and iliac veins. Dr. Beck incised the vein at different places subperitoneally, but did not reach pus. A few days later the pus appeared in the dressings. The patient recovered after many weeks of patient treatment. He summed up his remarks with the recommendation not to be too radical in dealing with primary infections. He noticed an intermittent edema preceding the permanent edema as a premonitory pathognomonic symptom of a deep thrombus. He recommended multiple incisions into deep thrombi. The second case was one of "Atresia of the Rectum" with a communicating canal into the bladder. The child was six years old, and cured after many operations. At first, the first day of life, a left colostomy was performed; six months later a resection of the coccyx with fastening of the intestine to the same, some months later rectoplasty and closure of vesicorectal communication, and three months ago closure of the colostomy.

Philadelphia Neurological Society.

At a stated meeting held December 21 Dr. G. E. Price demonstrated "A Case with Incomplete Brown-Séquard Paralysis Following a Knife-wound of the Neck." The patient was an Italian, who received an incised wound between the spines of the sixth and seventh cervical vertebrae, in the sequence of which he developed paralysis on one side of the body, with sensory changes on the opposite side. Marked improvement in the symptoms had taken place with the lapse of time. Dr. Augustus A. Eshner demonstrated "A Case of Hysteria Presenting Symptoms of Cerebellar Disease." The patient was a man forty-two years old, who presented difficulty in walking following emotional disturbances, with tinnitus and impairment of hearing and also impaired sensibility, but without motor weakness or changes in the eye-grounds. Recovery ensued under treatment with hypnotic suggestion. Dr. Eshner demonstrated also "A Case Presenting Symptoms of Cerebral Tumor, with Recovery." The patient was a huckster thirty years old, without venereal history, who suffered from vomiting, headache, vertigo, hemiparesis, with increased reflexes, but without changes in the eyegrounds. Improvement almost to the point of perfect recovery ensued after administration of active doses of iodide and mercurials. Dr. Joseph Sailer presented a communication entitled "Paralysis Agitans Developing in the Unparalyzed Side of a Hemiplegic." The patient was a woman who eight years previously had had an attack of apoplexy followed by right hemiplegia. Four years later symptoms of paralysis agitans began to make their appearance on the opposite side of the body. Various views were expounded on possible explanation of the association. Dr. W. W. Hawke demonstrated "A Case Showing Psychical Passive Apperception." The patient was a girl who had been employed at housework and in a mill, and who came to the city to do philanthropic work. She stated that she saw historic persons, whose images and surroundings she could call up at will. The case presented some of the features of dementia præcox, but it was decided that it was more likely one of dementia paranoides. Dr. David Riesman demonstrated "A Case of Probable Myasthenia Gravis in a Boy of Eight Years." The patient presented headache and causeless laughter, followed by diplopia, staggering gait, want of equilibration, obscurity of vision, ophthalmoplegia, unilateral palsy of the extremities, difficulty in swallowing, mumbling speech, nausea, vomiting, increased kneejerk, Babinski reflex, and congestion of the optic discs. Although the diagnosis of myasthenia gravis seemed probable at one time, especially in view of the marked improvement in the

symptoms that took place, it was decided, in view of the persistence of ocular palsy, left hemiplegia, with increased kneejerk on the affected side and Babinski phenomenon, that the condition was more likely superior polioencephalitis. Dr. T. H. Weisenburg demonstrated "A Case of Complete Ophthalmoplegia" in a girl about seventeen years old, in whom the condition had been present for several years. Dr. Weisenburg exhibited also a case of tabes dorsalis with optic atrophy, oculomotor palsy, and some want of action in the muscles of one side of the face and loss of taste on the anterior two-thirds of the same side of the tongue.

THE DIAGNOSIS AND SURGICAL TREATMENT OF GASTRIC AND DUODENAL ULCER AND THEIR COMPLICATIONS.*

By A. A. BERG, M.D.,

NEW YORK.

ADJUNCT SURGEON TO MOUNT SINAI HOSPITAL.

The intent of the writer in this paper is to consider the diagnosis and surgical treatment of gastric and duodenal ulceration and their complications.

The description, merits, and technical details of the various operations that are performed for the relief of these conditions will be ignored as far as is possible.

It probably seems to many of you, and especially to those who have had least experience with ulceration of the stomach and duodenum, that the diagnosis of this malady is usually easy to make; and so it is in the cases that present all the classical symptoms, viz., epigastric pain radiating into the back, heartburn, hyperacidity, hematemesis, melena, and a typical Head zone. Such cases, however, are not the majority, and we must not expect that the recognition of this disease is invariably simple and readily made.

There are firstly a class of patients who never present any symptoms of gastric or duodenal ulcer until some life-threatening complication, *e.g.* a profuse hematemesis or a perforation of the ulcer into the peritoneal cavity arises. As a rule, in such cases the ulcer is not situated at either of the orifices of the stomach, nor on the lesser curvature near the pyloric end, for with ulcers at these sites there are more or less well pronounced symptoms occasioned by the passage of the food across the ulcerated area or by the contraction of the pyloric or cardiac muscles. In patients of this class the diagnosis of ulcer will not be made, and should complications arise, we must always be in doubt as to whether they are dependent upon a long standing latent ulcer.

In the next place there is a class of patients who manifest, as the only sign of the gastric or duodenal ulceration, an atrocious pain in the right hypochondriac or epigastric region. There is no heartburn, no vomiting, no hyperacidity, no Head zone. The pain is severe, and often enough it incapacitates the affected individuals from doing their usual work.

If the pain is in the right hypochondriac region, it may simulate biliary and kidney colic, and subacute or chronic gall-bladder and appendicular inflammation. With gallstone disease, however, there is apt to be a history of preceding attacks of biliary colic, some of which have been attended with jaundice, and after some of them stones may have been found in stools. With kidney colic there is likely to be hematuria, often only microscopic in character, crystals of uric acid, oxalate of lime, etc., may be present in the urine, and during the attack there are often marked intestinal and gastric disturbances, such as nausea, vomiting, and obstinate constipation. With subacute or chronic cholecystitis and appendicitis there is usually a history of one or more preceding attacks of fever, pain, gastric disturbances, and tenderness over the appendicular or gall-bladder region.

A carefully taken anamnesis, the employment of the *x*-ray, cystoscope, and ureteral catheter and a thorough urinary examination will usually enable us to differentiate ulcer cases from those of biliary or tenal lithiasis; but in a certain number of them the exact diagnosis can be made only by exploratory laparotomy. We should not forget, furthermore, that gastric ulcer is quite frequently combined with gallstone disease, and that the contraction of peripyloric adhesions which have originated from gall-bladder, inflammation may occasion a stenosis of the pylorus that resembles clinically, in every detail, the pyloric stenosis which follows the cicatrization of a pyloric ulcer.

Many of the patients of this class become very neurotic and hysterical on account of the pain, and the symptoms arising from this disturbance of the nervous system may be so prominent as to cause us to look upon it as the primary trouble and the gastric manifestations as secondary thereto. Thus only recently the writer was called upon to operate a patient with perforated ulcer of the stomach, who had been treated by an eminent specialist for neurasthenia and dyspepsia. So commonly is this error made, and so little do the patients benefit from the treatment they receive for the neurasthenia, that Dr. Wm. Mayo has been led to state "that if the patients with neurasthenia and intense epigastric, or hypochondriac pain are referred to the surgeon, the latter will be able to restore them to perfect health by an operation directed to the cure of their gastric malady.

With reference to the diagnosis of the complications of gastric and duodenal ulcers, this will be easy if there is a previous history of such a condition. Thus, in a patient who has presented the symptoms of gastric or duodenal ulcer, a sudden tearing pain in the epigastrium or right hypochondrium, followed by rigidity of this part of the abdomen wall, tenderness in these regions, and rise of pulse rate, are very significant of perforation. In the writer's experience of eight cases of this complication, shock, vomiting, rise of temperature, and concentric obliteration of liver and splenic dullness have not been constant manifestations. In duodenal perforations it is to be noted that the point of maximum abdominal tenderness is frequently in the appendicular region, owing to the gravitation of the duodenal contents along the outer side of the ascending colon into the right iliac fossa. Inasmuch as duodenal ulcers frequently run a latent course until perforation occurs, this site of maximum tenderness may lead to an erroneous diagnosis of appendicular perforation.

*Read before the Harlem Medical Society, April 3, 1906.

In cases of hemorrhage from gastric or duodenal ulceration a previous history of these conditions enables one readily to determine from whence the blood comes; but in the absence of such a history it may be impossible to determine the origin and causation of the bleeding.

The most difficult of all the complications to diagnosticate are those which result from ulcers that run a latent symptomatic course until their healing and cicatrization occasions a benign pyloric stenosis, or until adhesions that form around them occasion disturbances in the patency and motor function of the pylorus, stomach, bile passages, etc., or until they have become adherent to and eroded into neighboring organs, such as the pancreas, gall-bladder, etc. Only by excluding all other causes for the condition at hand can we arrive at a correct anatomical diagnosis. These cases, however, always call for explanatory laparotomy, and the incision will clear up any doubtful points.

There is ordinarily no difficulty in differentiating ulcer of the stomach from cancer thereof, and yet when the ulcer has very much thickened edges and occasions a palpable tumor in the epigastric region the differential diagnosis may be attended with considerable difficulty, for the gastric symptoms in both conditions have much similarity, and the changes in the chemical composition of the gastric juice are very inconstant. The difficulty is all the more enhanced by the fact that it is just these ulcers with thickened edges that undergo cancerous degeneration. The only safe plan of procedure in these cases is to explore by laparotomy every palpable tumor of the stomach, and that without too much delay.

These few remarks indicate the difficulties that sometimes attend the making of a diagnosis of gastric and duodenal ulcer. Let us now look to the treatment of these conditions, and here we encounter another stumbling block and a rock upon which the internists and surgeons seem to split.

Gastric and duodenal ulcers, in their uncomplicated and in many of their complicated phases, have long been considered as belonging to those diseases that come under the pale of internal and dietetic treatment, and the recent suggestion of surgeons and some internists that surgical measures be employed in some of these cases has been received in a manner which is indicative of doubt as to the propriety and efficacy thereof.

First of all let us consider the treatment of the uncomplicated open gastric and duodenal ulcer. Leube, than whom no one is more entitled to speak of the medical treatment of this malady, before the German Surgical Congress of 1897 reported his results in uncomplicated gastric ulcer.* He stated that in 493 cases 74 per cent. were completely cured, 21 per cent. were improved, 2.4 per cent. died, and about 2.6 per cent. were unimproved. The cases that he considered as improved were freed of their pain, but at once relapsed when they stopped treatment, went back to their work, and resumed their ordinary diet. This is about the result that most practitioners with whom the writer has spoken and whose publications he has consulted achieve.

Evidently with the 74 per cent. of cases that can be and are cured by medical and dietetic means, the surgeon has nothing to do. But what about the 26 per cent. of cases that cannot be and are not relieved by these measures? What is to be done with them? Are they to be told that they are beyond medical aid; that they are to resign themselves to their fate, and continue to suffer from their disease until relieved by a kind Providence, or are they to be advised to resort to other means of help?

It is this 26 per cent. of cases that internal measures do not cure that the surgeon asks you to send to him for operation. He does not advise you to employ surgical treatment in all your cases of uncomplicated, open ulcer of the stomach or duodenum; on the contrary, he counsels you to exhaust all the methods of dietetic and local treatment before you consider operative interference; but if all these fail to bring relief and cure, then he urges you not to temporize further; not to surrender these patients to the pains and dangers that are inherent in their disease; not to repeat and repeat your medical endeavors until the patient's strength is exhausted and his morale dissipated, but to employ operative measures, and he promises you to restore a large percentage of such patients to perfect health and comfort. In this statement lies the main indication for the surgical treatment of open, uncomplicated gastric and duodenal ulcer. It answers one of the questions put to the writer, at a previous meeting of this society, when he presented a case of gastric ulcer that had resisted all medical therapeusis and was finally cured by operation, viz., "what the indication was that led him to employ surgical treatment."

Once you recognize the necessity and the adequacy of surgical interference in some cases of gastric and duodenal ulcer, you will at once ask what are the risks and what are the late results of the operations performed for this condition. You have a right to know what percentage of patients die directly or indirectly from the operation; for if the mortality from surgical interference is higher than that from the disease itself, then we are not justified in advising its employment. The death rate from gastric ulcer is usually put down as about 13 per cent., 6-7 per cent. from perforation and 5-6 per cent. from hemorrhage. In Leube's series of cases the death rate while the patients were under his care was only 2.5 per cent., but this does not take into consideration the ultimate outcome of the 21 per cent. of cases that were not cured by the medical treatment which he instituted. The 13 per cent. of deaths evidently do not occur in those 74 per cent. of cases that are cured by internal and dietetic means, but is confined to the other 26 per cent. In other words, one-half of the patients that are not cured by the non-operative measures succumb sooner or later to their disease. Now, inasmuch as the surgeon asks you to call upon him only in those cases which have not yielded to the internal and dietetic treatment, his results must be better than 50 per cent. mortality if he is to expect the patient and general practitioner to listen to his plea for the employment of operative measures. It is hardly necessary for me to say that no modern surgeon has anything like such a mortality. The Mayos, in a very large number of cases, report an operative mortality of about 2 per cent.; the writer, in the last three years, has had 10 cases, all of which recovered, and other operators have about the same results. All cases considered, the operative mortality is about 2 per cent. to 5 per cent. Thus we see that if the patient is not cured of his ulcer by medical means he stands one chance out of two of dying from the disease, if nothing further is done, and one chance in 20 of succumbing to an operation that is undertaken for his possible cure. This brings us to the consideration of the second portion of this query, viz., what are the final results as to cure of this malady by operation. Von Eiselsberg of Vienna has very carefully traced all the

*By open uncomplicated gastric or duodenal ulcer is meant an unhealed ulcer. It does not imply a bleeding nor a ruptured ulcer, nor one attended with any complicating condition.

cases operated upon by him during the past ten years.

Of the 40 cases that recovered from operation 38 were discharged from the hospital free of all symptoms; 14 remained well and had no further gastric disturbances; 13 were unimproved; 4 could not be traced; 9 died since their discharge, 6 of them with gastric symptoms. It is to be noted that in this series of cases operations, such as pyloroplasty, pyloric divulsion, etc., were performed for the cure of the ulcer that are to-day no longer done, their inadequacy for effecting a cure having been established; and, further, that of the 13 cases reported as not improved, some could have been cured by secondary operation.

Of the writer's 10 cases, done in the last three years, 7 have remained entirely well, 1 developed pernicious anemia two years after operation, 1 had to be reoperated several months after for recurrent symptoms that did not yield to internal measures and which seemed to be rapidly sapping the patient's strength and vitality, and from last reports she was well, and a third had slight recurrent symptoms one year after operation that readily subsided under dietetic and local treatment. If you consider that these reports concern only those cases that have not been cured by internal treatment, *i.e.* the 26 per cent. of cases that Leube reports as not amenable to cure by medical means, you must confess that much good is accomplished by operation in these cases. Can there remain, then, any doubt as to the advisability of treating surgically those cases of gastric ulcer that are not cured by dietetic and local treatment, and can there be any further excuse for waiting in these cases until the patient's strength is exhausted and operative measures thereby rendered far more dangerous and serious?

The writer has thus far only considered the treatment of the uncomplicated cases of open gastric and duodenal ulcer; let us now look to the treatment of the complications of this malady.

The most frequent and important of these is stenosis of the pylorus, due either to the contraction of the cicatrices of healed pyloric ulcers or to the contraction of peripyloric adhesions that result from the peripyloritis that frequently attends this condition. Only recently it has been stated here that the pyloric stenosis arising from these causes can be, and is, best treated by dietary regulations and gastric lavage. The writer readily concedes that the moderate grades of stenosis, viz., those in which the narrowed condition of the pylorus is fully compensated for by hypertrophy of the muscular coat of the stomach and which are not attended with material stagnation of gastric contents, nor with a considerable grade of gastric dilatation, can be and are successfully treated by these therapeutic measures. But unfortunately all the cases do not belong in this category. In many of the severer ones the pyloric orifice is almost completely closed, the stomach wall is atonic, the cavity of the viscus is dilated, and there is more or less complete stagnation of food within it; nutrition is markedly interfered with because the chyme cannot enter into the intestine for elaboration and absorption, both of which functions, as you know, are very slightly performed in the stomach. If such patients are put on a liquid diet and daily gastric lavage their condition is made more comfortable; their gastric distress, vomiting, and autointoxication from the absorption of stagnant material in the stomach is greatly relieved; but not even the most ardent advocates of this method of treatment believe that the cicatrices or perigastric adhesions can be absorbed or removed in this way. And while we are relieving the distress, and vomiting and autointoxication, what is happening to the nutrition of the patient? Gastric lavage and liquid diet, which latter is for the most part removed again by the lavage, are not particularly nourishing, nor are they calculated to promote that sense of well being and comfort that are essential for mental and physical work.

These unfortunate individuals, and they are truly unfortunate and most miserable, lose flesh and strength under this daily regimen of fluids and gastric lavage, become neurotic, and at last cast aside the advice of their physicians and seek the surgeon who promises them relief, no matter what the danger thereof may be. But what are these awful dangers that prompt this fear of surgical measures of cure, and that permit us to let these patients sink into a deplorable, neurotic, miserable, poorly nourished condition. The mortality attending operation, done at an early period when the patient's strength and vitality are good, is in competent hands about 2-5 per cent. Surely this is not commensurate with the pain, distress, loss of flesh, and strength, general discomfort, and inability to do work that is the lot of those who are treated with liquid diet and gastric lavage, nor is it equal to the mortality that ultimately attends this condition if not relieved by surgical means. With operation the patient must face a definite risk of 2-5 per cent., but if he survives therefrom he has a rosy outlook for complete restoration to health and enjoyment of life. Of 34 patients of von Eiselsberg, 32 recovered and 2 died; 20 were permanently cured; 3 were not cured, though one of these remained well for two and one-half years; 2 died some time after the operation, and in one of them there were no gastric symptoms before death, and 9 could not be traced. Without operation the individual has to expect a slow undermining of his health, a gradual loss of flesh and strength, increasing disability, neurasthenia, and, eventually, exhaustion. Can there under these conditions, be any doubt which course you, as practitioners, will advise your patients to follow, or which plan of treatment your patient will select! The surgeon's aid to these patients is a God-send, which only they can appreciate and recognize.

Perforation and hemorrhage are the two most serious complications of gastric and duodenal ulceration, the statistics of Leube showing that about 12 per cent. of the fatal cases are due to these causes. At the present time there is no one who will question the advisability of immediate operation in the cases of acute, sudden perforation, for we have learned that spontaneous cure from adhesion of neighboring parts to the floor of the perforated ulcer rarely, if ever, occurs. On the other hand, the cases in which the ulcer slowly and gradually eats through the walls of the viscus and in which the floor of the ulcer becomes adherent to neighboring organs before actual perforation occurs, thereby preventing extravasation of gastric contents into the free peritoneal cavity, are not urgent ones for operation unless a local abscess at the site of the perforation or sloughing, or necrosis of the adherent organ, calls for immediate surgical interference. Such patients as these latter, however, are the very ones that need operation for the cure of the ulcer, and they should be referred to the surgeon as soon as the local evidences of inflammation have subsided.

Clear cut as is the indication for immediate operation in the cases of acute perforation, so doubtful and uncertain is it in the case of hemorrhage. The writer knows of several eminent practitioners who have had a large experience with gastric ulcers and

have never met with a fatal case of hemorrhage therefrom, though they admit that in several instances it seemed as if the affected patient would die. Probably many of you have had the same experience, and in consequence thereof feel disinclined to advise surgical interference in these cases. And yet fatal cases do occur, as many as 6 per cent. of the deaths in this malady being due to this cause. The writer has seen several cases of ulcer bleed to death without surgical aid. We must admit then the possibility of a fatal issue from this cause, and we must concern ourselves with the question, firstly, is anything to be done to avert it? and secondly, when is it best to do it?

The writer has heretofore been guided in making a decision for operation in the face of bleeding from gastric or duodenal ulcer that was not to be controlled by medical means by the rules that were formulated by Mikulicz and Leube, viz., that operation is indicated (1) in the presence of acute, profuse, uncontrollable, bleeding, which places the life of the patient in grave jeopardy; (2) in the presence of frequently repeated bleedings, even if they are not profuse, that undermine the patient's strength, and lead to a chronic anemia.

The writer has never had occasion to interfere surgically for frequently repeated small hemorrhages from gastric ulcer, but in the past few years he has had 6 cases of gastric or duodenal ulcers that were suddenly complicated with several times repeated profuse hemorrhages. In four of these cases gastroenterostomy was done, and in two the expectant plan of treatment was pursued. In two the operation was done as a *dernier resort*, in enfeebled and exsanguinated patients, after internal treatment had failed to check the bleeding; both patients died shortly after the operation. In two the operation was done while the patients were still in comparatively good condition. These two recovered. Of the two patients who were treated expectantly one recovered and one died; the former of these two had commenced to convalesce from a diffuse peritonitis to which a perforated duodenal ulcer had given rise, and our minds were at ease as to the ultimate outcome, when suddenly there were, in rapid succession, three enormous bloody (tarry) evacuations from the rectum. His pulse rate jumped from 92 to 148, became thin and compressible; his respirations were sighing; his color extremely pallid, and his heart sounds feeble. The hemoglobin of his blood was 19 per cent. The experience I had gained from the two other cases in which, in the face of such a desperate general condition, a gastroenterostomy had been established under cocaine anesthesia, led me to refrain from and advise against operation in this patient. This decision proved to be a wise one, for, under medical treatment, the bleeding did not recur, and the patient made an uninterrupted convalesence. The fatal case that was treated expectantly was a woman, several months pregnant, who had suffered from the symptoms of gastric ulcer prior to her marriage. There had been but little nausea and vomiting during the pregnancy. Several days prior to the time I first saw her with Dr. Libman, she commenced to vomit blood. This was repeated several times, and the family physician with whom Dr. Libman had seen the patient requested him to take her into the hospital. On her admission she vomited about 16 ounces of fresh blood. Her hemoglobin was about 40 per cent., her pulse rate about 120, and not of good quality. In spite of absolute rest to the stomach and the careful use of internal remedies, the hematemesis recurred, and surgical interference was advised, but rejected by the family. Thinking that perhaps the pregnancy excited the vomiting and hematamesis, Dr. Vineberg was asked to see the patient; his advice to terminate the pregnancy was followed, but in spite of this and all other means the bleeding continued and caused the death of the patient.

Of the operated cases only in one was an attempt made to locate the bleeding vessel and directly control it.

When the stomach was opened the bleeding had ceased; the ulcer was readily located; it was on the posterior wall immediately over the celiac axis, Its base was cauterized with the Pacquelin, and then an anterior gastroenterostomy was established. In this patient the search for the ulcer somewhat prolonged the operation, which was done under cocaine anesthesia. In the other three cases no attempt was made to find the bleeding vessel; the writer contented himself with rapidly establishing a posterior gastroenterostomy. In none of the four cases that were operated upon was there any evidence of further bleeding.

The method in which a gastroenterostomy checks the bleeding is not quite clear, but probably by putting the stomach at rest it permits the bleeding vessels to contract and retract within their sheath, and the clot which forms over them is not constantly displaced by the peristaltic movements of the viscus. We must not think, however, that gastroenterostomy succeeds in stopping the bleeding in all cases. There have been reported in the last few years about 6 cases of fatal bleeding from gastric ulcer for which a gastroenterostomy had been done several days prior to the onset of the bleeding. In these cases the ulcer was probably surrounded by much inflammatory thickening, which prevented the eroded vessel from contracting and retracting. In cases of ulcer of this kind, complicated by bleeding, it is better to excise the ulcer-bearing area than trust to gastroenterostomy to check the bleeding.

The good effect on checking the bleeding from the stomach, from causes other than ulcer, that is to be obtained by putting the stomach at rest by gastroenterostomy was seen in a case of the young girl with repeated and profuse hematemesis from cirrhosis of the liver. After the gastroenterostomy there was no further bleeding.

The number of cases with sudden, profuse bleeding from gastric and duodenal ulcers that the writer has had is still much too small to permit of his forming any decided rules for future guidance in these cases. A review of the cases, however, may afford a hint that may help in the successful management of patients whose lives have suddenly been placed in the gravest jeopardy by the occurrence of this complication. Of our six cases four were in most desperate condition as a result of the bleeding; one declined operation; one had had repeated hemorrhages (hematemesis and melena) for six days, and just before operation had a pulse of 156, soft and thready in character, and a hemoglobin percentage of 30; one had had repeated hemorrhages for 12 days; her hemoglobin was less than 25 per cent., her pulse was 140 to the minute, soft and scarcely perceptible, and her sensorium was clouded. In both of these cases the attending physicians had called upon the surgeons to stop the bleeding, only after all internal measures had failed to accomplish this, and as a *dernier resort* gastroenterostomy was done. Neither patient reacted from the laparotomy; death occurred in one case fourteen hours after the operation, and in the other about ten hours after. These two experiences would seem to show the futility of operating when the patients are in such

desperate condition. They are scarcely able to withstand the operative shock and rapidly succumb to it. and that whether a general anesthesia has been administered or not. When the patients are in such condition, it seems to the writer that it is better to continue with internal measures than to do any operation, no matter how simple it is nor how rapidly executed it may be. This view would seem to be borne out by our fourth case, in which the hemorrhage occurred on the tenth day after a successful operation for the closure of a perforated duodenal ulcer, and for which no operation was done.

The good effect of gastroenterostomy in instantly checking bleeding in two of the writer's cases shows what can be accomplished in these cases when the operation is done at a time when the patient is in fair condition. The hemoglobin in these cases was about 40-45 per cent., the pulse, though rapid, 110-120, was good in quality.

If the writer summed up the impression made upon him by the observation of our own cases he would say that operation is not advisable when the patient's general condition is bad, the hemoglobin very low, 19-20 per cent., and the pulse not very rapid. In such a condition the operative shock. no matter how slight it may be, whether or not it is combined with the added depressing and hemolytic influence of a general anesthetic, is sufficient to cause the death of the patient. It is far better, in such cases, to trust to internal remedies and complete rest, induced by morphine, to check the bleeding. When, however, the patient's general condition is still good, and the hemoglobin count is about 35-40 per cent., he would strongly advise immediate operation, either excision of the ulcer, if it has indurated edges, or gastroenterostomy. This will have a double effect; it will check the bleeding and so remove the immediate threatening complication to life, and it will further favor the removal or healing of the ulcer.

Acute dilatation of the stomach, secondary to pyloric stenosis from cicatrized pyloric ulcer, or contraction of peripyloric adhesions, is one of the rarer complications. The cases are still too few to permit us to state whether it is more advisable in these cases to resort to immediate gastroenterostomy, and thus drain the stomach, or to accomplish the latter by repeated gastric lavage. From the experience gained in two cases of acute dilatation of the stomach due to other causes, and treated by repeated gastric lavage, the writer thinks that this mode of procedure is the more advisable, at least in the acute stage. Of course, eventually a gastroenterostomy or pylorectomy would have to be done.

The writer hopes that in these brief remarks he has put before you the present status of the surgical treatment of gastric ulcer and its complications. The subject is a new one, bordering on the line of medicine and surgery, and only by the concerted efforts of the internist and surgeon can the full development thereof be achieved and the best results accomplished.

923 Madison Avenue

"RHEUMATISM" AND ITS TREATMENT.

By F. J. WALTER, M.D.,

KRAMER, IND.

We have made a poor diagnosis when we pronounce a case of rheumatism. The term directs us to no pathological condition, though, like some other terms in our vocabulary, it serves to satisfy the patient, while confusing the mind of the physician. Why should we not be more definite and apply the exact meaning to the condition as: arthritis, synovitis, neuritis, and autointoxication with muscular pain? This covers most of so-called "rheumatism." "Autointoxication with muscular pain" is most confusing, but in reality is due to the absorption of the products of indigestion, from our habits of living, no doubt. Note how nearly 99 per cent. are constipated or have abundant evidence in the urine of some absorption of toxic products. Here we may have the lithemic condition (if one will call it such), acute conditions coming at once to our notice from the lowered resistance after cold or exposure.

In arthritis we have an infection made to flourish by the above condition. Fertile soil we say. While we do not know the definite infection in arthritis or polyarthritis in every case, often it is a mixed infection and never can be clearly isolated. The gonorrheal and tuberculous joints give us a definite picture. We put them off by themselves as understood; this is not right, for the other forms of arthritis have many more characteristics than are shown on a superficial survey. The majority of patients with arthritis have a history of some infection, and many old persons give us the history of grip, which is an infectious catarrhal fever. Then we have tonsillitis, pneumonia, typhoid fever, and this class of infections. Some avenue of entrance can usually be discovered, if only the cavity of a tooth. We know we can have pneumonia of a joint and not have it in the lungs. In other words, the pneumococcus may go to a joint and escape the lungs entirely. We call this "acute rheumatic fever" or "acute articular rheumatism," while in reality these terms apply to acute polyarthritis, though all cases of polyarthritis are not produced by the diplococcus of pneumonia. Also we have our typhoid, gonorrheal, tuberculous, pneumonic, and postgrippal forms of arthritis. Arthritis deformans is an infection (progressive in those of low resistance) and we do not know just what germ causes it; perhaps not always the same bacterium; but with it we have a trophic disturbance of the spinal centers, bilateral. There is every evidence of nutritional change in the muscles, joints, and nerves. These cases are years coming on; at times with long history of indigestion and urine loaded with urates, uric acid, and oxalates, and other evidence of incomplete digestion, such as flatulent dyspepsia, anemia, and weakness. Now, we must associate in our minds infection, inflammation, and poor nutrition with feeble powers of absorption and what is absorbed of poor quality; then we have an intelligent idea of arthritis deformans. We may have tabetic and hysterical joints. Is it not better to distinguish between all forms of arthritis and classify them than simply to diagnose "articular rheumatism"?

Of neuritis we have several forms: traumatic, infectious, toxic, inflammatory (without a definite infection known), infiltrations, reflex, and from pressure. Of the toxic forms of neuritis we have those of lead, arsenic, alcohol, and autointoxication, all affecting the nerve trunk, sheath, or the periphery; the sciatic nerve, or any other, may be the one chosen with a variety of sharp, lancinating, or burning pains. What is the use of adding "rheumatic" to the already better diagnosis of sciatic neuritis, peripheral neuritis, or neuritis of the anterior crural nerve? To be sure, we have muscle contraction from muscle irritation. Look out for neuritis in the diagnosis of intercostal neuralgia, and other local persistent neuralgic conditions, and look out for tabes dorsalis in the diagnosis of neuritis of the legs.

In the muscles we have nerves. It may be a neuritis of some finer twigs causing the myalgia. Now, what shall we do with "muscular rheumatism"? In the muscles we have a large surface for circulation and absorption, and we have the absorption of the toxic products above alluded to—the products of indigestion; also sprains and trauma. It is just here that it is most difficult to apply the proper diagnosis, as we are so prone to say "muscular rheumatism," yet we can fathom the cause and apply a term meaning more than the term "rheumatism." Some say "give the salicylates, and if they relieve it is 'rheumatic.'" I believe that the salicylates act only on the pain as an anodyne. Many cases are apparently cured because the salicylates and salol are such good intestinal antiseptics and antacids. We can apply our electrical tests here and find some cases of neuritis. In these cases of autointoxication the system is highly acid. I find nearly every case turning litmus red in the mouth. The dentist will notice it in the tartar of the teeth before the definite pains come on. How this goes to prove saturation and absorption of the products of fermentation! In local conditions of the feet don't forget "flatfoot." With a stock of foot arches on hand, of every size, one can cure many cases of so-called "rheumatism" of the feet. From the practical experience of 3,500 cases a year I am learning that uric acid, as well as leukomains, purin bodies, oxalates, urates, cystin, phosophates, indican and decreased urea are symptoms of this condition and somewhat of a barometer of the case; uric acid is not the cause. With poor elimination these things accumulate and are influenced by diet. These products certainly are found most often in those of sluggish habits and sedentary lives. These products of decomposition of the food circulate in the blood and are irritants to cell life and intoxicate more or less the brain centers as well as act as irritants to the endothelium of the kidneys, producing "Bright's disease" and bladder irritation. As a guide to our treatment and diagnosis, it is well to keep in mind the amount of toxemia, the resistance of our patient, the presence or absence of infection, the degree of inflammation, the nutrition, the vitality, the social conditions, the character of the food, the amount of exercise the patient can and should take, and, what is very important, glandular action and elimination.

Proper food, intestinal antiseptics, tonics, antacids, and active elimination by every means of escape are very necessary. The skin is a larger organ than the liver, and elimination by its wonderful excretory glands is not to be overlooked. This is why hot baths and mud packs do so much for this class of cases. These people are, or have been, large eaters, fond of the good things of life, and have "the best in the land" on their tables, but they have been unable to take care of it: what is more, they do not know in time that they are not digesting and eliminating properly. They will remark that a selected diet is excluding just what they like, and yet this does not mean that we have to starve them. It is not easy to find what will produce the least evidence of autointoxication, though by patience and individualizing we can in some little time produce gratifying results in most obstinate cases. In gout one will find the patients "overloaders," and it is but another phase of this same condition with a lowered resistance and an acute infection developing that produces the acute attack.

Treatment.—Physicians differ greatly in dietetic matters. Many patients will be found on a starvation diet when they most need nourishing food. "Diet" does not mean starvation, but it does mean the selection of good food to suit the individual. With anything like an agreement by physicians as to the cause of these so-called "rheumatic" conditions, the chances for a common ground will be better. To individualize the diet we must exclude foods which in a given case cause fermentation, pain, distress, anorexia, gastric or intestinal distention, acidity, constipation, or myalgia as nearly as is possible; for example the starches and sweets ferment in those of sluggish motor power or having nervous dyspepsia and cause flatulency. Tomatoes and strawberries are frequently followed by a serious aggravation of the myalgia and the urine will be found loaded with oxalates. Pork and veal are both a great tax on all the parts concerned in digestion and take hours to be assimilated, and unless the motor power is extra fine they should not be given; but few can omit meat for a long time and not show the need of some strengthening food. Most persons can take mutton, chicken, and small amounts of bacon or beef. Some persons cannot take fried food at all. The nitrogen of meat is not so bad; it is the products of incomplete digestion of the food (purin bodies, xanthin bases, or leukomains) that are so toxic. Many cases of sluggish bowels are greatly helped by the cannon-ball massage of the abdomen and the use of dates, figs, or prunes daily. Acid conditions of the contents of the intestines sometimes keep up the constipation which exists in over half of these cases. Acids will increase the acidity as well as the fermentation. Lemons are the least objectionable, and with some improve the condition by being converted into an alkali.

Diet alone will not do everything, but every means in therapeutics must be used to bring about normal physiology in every disease process. It seems to me that we cannot too strongly urge patients to use every means and impress the use of cooperation and combined methods and let the patient not feel that diet, baths, massage, electricity, climate, or one or two means can bring about a cure. Great patience, combined with persistent methods and a clear insight into the cause, by physician and patient, are necessary to bring about the disappearance of symptom after symptom. Too much stress cannot be given our social conditions as a factor in the etiology; our methods in the preparation of foods; highly seasoned foods; food that needs but little mastication; the enormous appetites of so-called "rheumatics"; in general, how our farmers, during the winter (their season of inactivity), keep their tables loaded most bountifully, and how, in spite of indigestion, people are inclined to "overload" in eating.

Combined with diet we use baths of various kinds, drugs, exercise or rest, electricity and light, climate, massage, vibration, topical irritants or anodynes, proper clothing, operative measures, water drinking, proper surroundings, heat and cold, besides all the attention we can give to the nervous system, going back of all this to every avenue of possible infection. I am satisfied that some infection may come through the glandular tissue (similar to tonsil tissue) of the appendix vermiformis, through the mucous membranes of the head and throat, through the tonsils, teeth, ulcerations, any suppurating focus, and after any infectious disease. Before taking this systematically I wish to say that at "watering resorts" one sees a large class of patients who are "last resorters"; people who have tried everything ever suggested or thought of at home, and usually none of them long enough to do any good, and often the very wrong thing. If we poor doctors had the

chance of our prescriptions being renewed even as often as the six bottles of patent medicine for five dollars, our well-regulated prescriptions would have a chance to assist a great deal more than they do. It is seldom that we hear of a chronic case taking more than an eight ounce prescription. That tried, many times they feel in their own minds they have been to the end of the resources of their doctor. It is a good plan to follow, in taking a case from another physician, to try some form of relief other than the salicylates, if he has been unsuccessful, and you would be successful, for the chances are that he has given the salicylates. I try to keep my patients busy with a lot of things and never discourage the use of any harmless method or topical application. It is not "having faith" in a physician that is necessary to bring about good results, as we so often hear; it is the cooperation that faith brings which produces the results.

Baths do their part by elimination, equalizing the circulation, relaxation or stimulation as desired, and at resorts in placing the patient where he will make a business of getting well. The best results come from long baths at an even temperature. Too hot baths cause a marked aggravation by distributing through an excited circulation these xanthin and other toxins; extra hot baths cause fainting and general aggravation, at times driving the patient to bed. All this can be avoided by more, longer, and cooler baths. Patients will want the temperature warmer than is best for them, in the hope of hastening matters. A fever of 102° is a contraindication for a very hot bath, and many times it is best to omit the warm bath for a day when the fever is high, depending upon other measures for a few hours. Shifting pains and increased swelling under bath treatment are looked upon with favor. Localized, persistent inflammation is more stubborn and slower. Any compensated heart can stand baths if due consideration is used. The head should be elevated and the bath cooled down somewhat quickly and of short duration. Baths are indicated in all cases of autointoxication unless there is too much prostration or high blood pressure with arteriosclerosis. In such doubtful cases it has been my habit to satisfy myself as to the amount of pressure to use Stanton's blood-pressure indicator. Excluding these cases and the dilated hearts, the baths cannot be other than a sheet anchor in the treatment of the so-called "rheumatic" conditions. My greatest experience has been with the mud baths, concerning which, to quote a noted author, "a great feature which commends itself is the evenness of the temperature and absence of chill." With a water and mud bath side by side the patient who is suffering a great deal of pain will totally ignore the water bath and express great gratification and satisfaction of relief from the mud. It is most important that the use of the baths should be associated with the drinking of quantities of pure alkaline water; during the baths three or four glasses of hot water should be taken slowly. This promotes perspiration and neutralizes acidity of all the secretions. Too much water must not be taken just before the meal time or for two hours after; then never more than two glasses (slowly) at a time, avoiding all danger of dilatation of the stomach. From eight to twenty glasses can in this way be taken in a day. It is best not to drink large quantities before retiring, as it excites the kidneys unduly and does not give them or the patient the nightly rest. Fifteen or twenty glasses a day for any length of time is too much of a tax on the endothelium of the kidneys, unless assisted by baths. When the days are warm and dry greater quantities can be eliminated through the lungs and skin by evaporation. Less should be drunk on damp days, less should be taken in cases of organic heart disease, high blood pressure, and splanchnoptosis. Large quantities increase the production of fat, and many fat people are aware of this and do not drink water enough for good health. Most persons do not drink water enough, and the need of doing so simple a thing is hard to impress upon them. In cities it is practicable to prescribe distilled water, with certain salts and drugs added at times, to be mentioned later. Most persons do not know that a healthy and active condition of the skin will increase their resistance to many infectious diseases. This wonderful organ expels what is left behind by incomplete action of the kidneys, liver, bowels, and lymphatics. Too much diuretic action by any water will cause constipation. Niter cannot be given for any great length of time without carrying off enough fluid by the kidneys to react on the bowels and cause dryness of the contents and a constipation similar to that which is associated with diabetic conditions. A diuretic and a cathartic never act well at the same time; one should never give them the same day and expect full action of the diuretic. Large quantities of any pure water will act as a diuretic, and this is especially true of an alkaline water, so you must watch the constipation so apt to follow. This constipation, however, does not seem to follow in all cases.

Exercise is a great and important problem in stout, so-called "rheumatics" with sore, inflamed joints—especially heavy persons with arthritis of the knees or ankles. We cannot conscientiously advise these persons to walk and irritate an already inflamed surface, nor can we advise active massage in such cases. Inflammation demands rest. Therefore I say to such individuals: "Be out in the air all you can, drive when the weather permits, bathe all you can, watch your diet, take such remedies as are prescribed for you, and as soon as the evidence of inflammation is gone, and the soreness and swelling disappear, begin to walk and exercise, then take your massage under the direction of a competent physician." Muscular stiffness and pain that is not a neuritis demand exercise, bending, kneading, percussion, and friction, but inflammation never calls for such methods. The best way to limit an infection is to put it up in a splint, and this applies to arthritis. Exercise in autointoxication to assist glandular inactivity is most important; it would be advised in arthritis and neuritis if it were not for the local conditions. When a patient comes to you with swelling and every evidence of inflammation, put him on crutches or in a wheel chair. This will be seriously objected to, though in a few days the results will be evident, and the patient will thank you for one of the first positive indications of cure. Systematic exercise may come later, the use of dumbbells, clubs, walks, and massage will be indicated as soon as this stage is passed. Then start your movements up to the point of slight soreness again. In this way you will prevent adhesions; or if some have formed, break them up before they have become organized. Some old and neglected plastic joints can be broken down and worked every day; when once you start, never stop until you get as near perfect motion as your judgment tells you is possible. It is best to be firm and discourage exercise or motion in neuritis of the sciatic nerve and to tell such patients to lie around, go to bed a part of the time (as it is hard to sit) keep pressure off the nerve, avoid walking, or go on crutches when they do walk. Massage or vibration is not indicated

manipulation until all acute inflammation, pain, and soreness are gone. Complications and cramps will in this way be avoided.

Having spoken of baths, waters, exercise, and rest, let us speak of the use of electricity. The results in a few cases cannot be taken into account, for under no treatment at all disease often makes sudden and unmistakable changes for the better. In general the faradic current, while a stimulant, will be found to aggravate most of these muscular, nervous, and joint lesions. The immediate results often are palliative, but improvement is seldom lasting. It is difficult to select cases which are curable by electricity, as a remedy in these complications requires some positive indications, and the action of electricity is too uncertain. Faradic currents are certainly disappointing in their results. The galvanic current, however, I consider one of the most useful means we have to soften and absorb deposits and infiltrations, paying attention to the action of each pole. The high-frequency, high-tension, static current is a good sedative and I have faith in it in some cases. The white-light or high-power incandescent ray has done some wonderful things for me in the relief of pain, and as an anodyne in some local inflamed conditions. I can report no good results by the use of the *x*-ray except as a means of diagnosis. Cataphoresis with cocaine and opium is a means of relief for acute painful conditions. The static spark irritates most cases. The breeze is with the proper pole somewhat of a sedative.

We must recognize massage as one of the best treatments for the so-called "rheumatic" conditions that we possess when followed out properly, at the proper time. Massage, or systematic manipulation of the tissues of the body, is one of the oldest means employed in the treatment of disease, dating back as far as 3,000 years B.C., being used in the Orient at that time. It has been used, associated with more or less medical treatment, by all nations; but in the present age, from some unknown cause, it has been singled out as a science of its own and is applied to the treatment of all disease, regardless of the science of medicine. It lays special stress on the treatment of this class of troubles, but can no more stand alone here than electricity. Medical men must be broad enough to clothe their minds with more than one idea in the practice of this interesting profession. This is why radical sectarian physicians are distinctly narrow. First the system must be rid of the toxins and active inflammation before one can think of manipulation, else we elevate the temperature and increase the liability to organic heart trouble and other complications; if massage is employed too early the patient is left in a weakened condition and the liability to infection is greatly increased. Pain is always increased by the most scientific masseur in active inflammation, though it may "numb" the process for a few hours. In a localized inflammation of a joint, in the passive stage, where there is stiffness or ankylosis, massage of light, stimulating character should be used, great care being exercised not to increase the pain or set up additional inflammation, but some hyperemia (to such a degree as to arrest adhesions). One should have a trusted masseur to be certain of this. In chronic cases where there is ankylosis or adhesions about the joints, nerves, and muscles without appreciable soreness, massage is nearly always of benefit. It sets up light inflammation, which promotes absorption and permits motion, doing all those things hoped for without much aggravation. Active motion must be employed and continued, though the manipulations should be guided by the soreness produced. Following the above lines of manipulation, the gonorrheal joints will be found to be (in the subacute and chronic stages) the ideal subjects for massage. After the long relaxing bath will be the most favorable time for treatment. This should be followed by rest in bed for an hour or two. Cannon-ball, abdominal massage will, as mentioned before, be useful for constipation. A tuberculous joint must not be massaged.

Many cases of this form of autointoxication are better in a warm, slightly humid climate, because the skin is kept active and constant elimination is induced. The dry climates of Montana, North and South Dakota send us most of the so-called "rheumatics," the Gulf States comparatively few; the Southwest has less changeableness and is perhaps the best all-around climate we have in the United States for infections, and as a place to be out of doors and induce resistance. Too high an altitude should not be sought where the nervous system is in the least involved, as the integral parts of the nervous system must be complete or convalescence will be slow. These infections and "acid turns" will be found everywhere and a study of the social conditions must be kept in mind. Even the Southwest would not do if the particular section were subject to too much dust, because of continuous throat irritation and infection from the head or throat. California is said to have every climate of the three zones; a few desirable places can be found, but the cold nights and the dampness in certain seasons near the coast make it favorable for infections, and the "barometer acid" patient is likely to have considerable myalgia. The West Indies or Florida, down at least 300 miles south of Jacksonville, are among the best places to be found anywhere during the winter for old persons and patients with heart lesions, particularly those with bronchial affections and subjects inclined to pneumonia. The coast from New Orleans to Savannah is given as the region with the fewest kidney diseases of any section of the United States, due largely to the soft water and the constant excretive action of the skin. This is always favorable to so-called "rheumatics." In any climate the surroundings ought to be congenial; worry is most depressing and disastrous. The subjects of nervous cases in particular must be kept out of doors, and this is not practical in the North, which is a good reason for sending such persons as can afford it to the South; and I think it will be found (fortunately for them) that the most "nervous exhaustion" is present in the families of the well to do. The region west of the Cascades in Washington and Oregon, except in the very rainy season, is better than the region through Wyoming and Montana. Wind is the worst enemy of neuritis, and this includes sciatica. A study of the government reports regarding the averages for the year at all of the most important stations in the United States shows some interesting figures. If one studies the chart, which is a complete summary for the year 1902 of the velocity and direction of the wind, the number of clear, cloudy, and partly cloudy days, the average rainfall in inches, the extremes of temperature, the number of gales (storms in which the wind exceeded forty miles an hour), the average humidity, fog, and the barometric pressure, it will materially aid in the selection of a proper climate for anyone. It will take but a glance to note that Roseberg, Oregon, has the least wind of any point in the United States (for the year 1902), and the Pt. Reyes Light off California the most. Chicago and Buffalo, as well as our own section, are extremely windy when compared with other points.

A country with much wind is apt to have extremes of heat and cold, as is found along the Lakes. This is to be avoided, as it suddenly checks the perspiration. A section with a large number of cloudy days, much humidity, and a high barometer is better than one of sudden changes. The "Land of the Sky" in North Carolina is delightful throughout the year and beneficial where altitude does not disagree, except for a couple of months in the winter, when it is frequently rainy and chilly. These months can advantageously be spent in southern Florida. In the matter of clothing, wool is much better than linen, silk, or cotton, to be worn nine months in the year. The more changeable the climate the more need of wool. The section sending to us the greatest number of so-called "rheumatics" for treatment is the Northwest.

I now want to speak of the social conditions more in detail. Lack of the proper clothing when society calls for low-neck and short sleeves in many women, predisposed to neuritis or myalgia with autointoxica-

tion, will bring about an attack. Many of the vocations of men require sudden changes of temperature when the body is not properly clothed, and account for the same thing. The kind of food, the way it is prepared, and eating, whether the previous meal has been properly digested or not, out of a sense of propriety, or duty, are accountable for fermentation and constipation. In a short time it looks as if the race would not need teeth from the lack of use for them, from having our food almost void of anything solid. Overindulgence is practised and admitted by most of us, and no one cares to be the pioneer in making a radical change of this whole complicated system. In the early days of the settlement of this country the prevalent disease was "fever and ague", we heard very little about "rheumatism." The fact was plainer and our forefathers were men who had to work actively out of doors; there was very little to make the organs torpid. No one will deny that each nationality has its diseases and this brings to our notice the diseases of to-day. A great amount of importance can be given this question of our surroundings. The disease of the age is so-called "rheumatism." One can hardly meet a soul who will not tell of having myalgia occasionally. This is the age of overindulgence. It is the age of overfeeding, overtaxing the nerves, the age of taking chances, the sacrificing of strength and health for business and "the dollar." It is with prosperity that we expect these things. The common people have luxuries and the rich have more banquets. Here in the temperate zones we have food from every part of the world on our tables, perhaps at the same time. There is lack of exercise of the proper kind at the proper time, or too much exercise of a wrong kind, with inattention to the kidneys and the bowels as well as no thought of eliminative baths. The overheating of our houses during the winter with a lowered resistance and associated prevalent infections during the spring bring to a climax latent troubles. For those who lead sedentary lives, two meals a day for a course of time is of benefit, as inactive habits are responsible for much autointoxication. In my opinion it will take radical measures to change these things. We all have patients who will not give us positive evidence of autointoxication and this should lead us to a better diagnosis by obtaining a history of a different kind. If we were to speak of the differential diagnosis we would include every possible kind of arthritis and neuritis, monoplegias, as we have in some forms of tortipelvis, central and peripheral nerve lesions, the characteristic inflammations of sacroiliac disease, hip-joint disease, and coxalgias as well as "crick in the back" and local diseases, gout, "joint mice," arthritis deformans, osteoarthritis, trauma of every sort, and the condition commonly called "rheumatic" which suggested this paper.

Finally I wish to speak of [illegible] of some of the most effectual drugs and [illegible] tions.

First of the specific [illegible] mention the Bier treatment because of recent experiment with it. Cases are being reported with most satis-

factory results. The principle is that of hyperemia producing absorption, followed by resolution. This is brought about by constriction of a rubber bandage above the effected joint, to be worn all night, or part of the day and all night for a period of from ten to fourteen days. It is not to be used in acute arthritis, but as a rational treatment for the slow, chronic inflammations. Baths will produce a mild degree of hyperemia and perhaps some of the good results from the Bier treatment reported in the journals have previously been brought about by baths. This treatment is as yet in the experimental stage and experience will tell us its worth. All pus joints should be opened and drained, splints or plaster used, and the joint placed in a position to be of the most use in case it should become ankylosed. Exudations and soft noninflammatory swellings are best treated by the use of the elastic web compression bandages, first applying a cotton bandage below to prevent swelling of the parts. The operative treatment of sciatic neuritis should be limited to the removal of all sources of reflex and direct irritation, and to the securing of rest. Have all piles removed, attend to rectal strictures or any growth in the region of the nerves, immobilize sacroiliac disease, keep the principle of "inflammation at rest" in mind. It is not best to advocate nerve stretching, vibration, or electricity in the acute stages of neuritis, some few good reports to the contrary. Salt injections along the nerves are helpful, and so are hot air and electric-light baths. It is certainly of the utmost folly to speak of specific drugs for these numerous complications. Other means of therapeutics must be combined, else we are planning a "hit or miss" campaign of the worst form. The whole picture must be studied and stress laid upon prophylaxis. One will find himself at times treating the nose and throat or sending a patient who can afford it to a suitable climate as a prophylactic measure. In their order I will enumerate the class of drugs usually used to treat a developed case, viz., Intestinal antiseptics, eliminants, (cathartics, diuretics, diaphoretics), hepatic stimulants, antacids, tonics (glandular, nerve, and muscle), alteratives, anodynes, antiphlogistic applications, counterirritants, antipyretics, antispasmodics, spinal sedatives, cardiac stimulants, and serums. An admirable combination of an antacid, intestinal antiseptic, and anodyne is a 5-grain capsule of equal parts of aspirin and acetphenetidin to be given as required. For acute, painful conditions it will be of daily use. In extremely painful localized inflammations add ¼ to ½ grain of codeine. Salicin has its advocates, but has no advantages and some disadvantages. The sulphocarbolates of lime, zinc, and soda, with saline for bowel elimination, have many followers, and constitute good treatment. As laxatives we can use sulphur waters, salt water, magnesium sulphate or citrate, Rochelle salts, almost any aperient water, cascara, or combinations for complications of calcium, lithium salicylate, and colchicine.

An active saline is magnesium sulphate 1 lb., aromatic sulphuric acid 1 oz., essence of gaultheria 2 drams, water 1 qt., mix, filter. Dose:—from one to two ounces occasionally. Of hepatic stimulants, calomel or the following: podophyllin ¼ grain, leptandrin ½ grain, iridin ¼ grain, extract of nux vomica 1-16 grain, pulv. capsic 1-3 grain, mix. Antacids: alkaline waters, aspirin, sodium bicarbonate. Throat and nose prophylaxis should consist of the free topical use of peroxide of hydrogen glycerin, and water, equal parts as a spray and gargle, followed by alkaline antiseptic washes and oleaginous antiseptic sprays. Tonsillitis will sometimes be aborted by the use of equal parts of oil of sweet almonds and liquid guaiacol as a spray; this should be repeated. It is an irritant, but the irritation passes off soon and will produce gratifying results. Camphor and menthol in a hydrocarbon oil can be used freely for the same symptoms. Hamamelis, calendula, and pine oil, for the more chronic inflammations, will be found useful. Surgery and the cautery may be required. Of the tonics, those which build up the nervous, muscular, and glandular tissues should be combined. The hypophosphites, phosphoric acid (in neuritis and neurasthenia), hydrastis, alkaline elixirs, quassia, gentian, syrup of the iodide of iron, or iodine. Of late formic acid has been used for muscular fatigue and as a muscle tonic. Olive and codliver oils are nearly always indicated. Strychnine should not be given at all in hyperesthesia of spinal origin. This drug is not well borne in many nervous conditions. Fowler's solution in wine with colchicine and intestinal antiseptics should always be considered. The iodides and mercury lead the list of alteratives, bichloride 1-40 grain three times a day. Of the anodynes use aspirin, acetphenetidin, codeine, morphine, and local applications, such as ointment of the following, applied under cotton: oil of gaultheria, menthol crystals, and the tincture of opium of each; one dram, liquid guaiacol one-half dram, lanolin four ounces. A liniment of the following applied hot under cotton properly held in place by a bandage, is of temporary benefit: oil of gaultheria, menthol crystals, tincture of aconite, tincture of opium, of each, one dram chloroform and soap liniment, of each two ounces, and glycerine four drams. Antiphlogistic applications of hot mud, clay, and glycerin. Serums are as yet in the experimental stage and the results of such experiments will depend largely upon the isolation of specific germs and the methods employed in the manufacture of the serum. We are making some experiments in the use of antigonorrheal and streptolytic serums, but we are not yet prepared to give our results. It is a great field and promises much. Plasters of belladonna, rhus toxicodendron, and bryonia are palliative. It is seldom necessary to use irritants; the best is the tincture of iodine.

Conclusions.—(1) The various infections will account for every form of so-called "rheumatism" except muscular and that is an intoxication. This intoxication accompanies or precedes most articular and some nerve infections.

(2) The term "rheumatism" is a misnomer, but must be retained for a time, until real facts are appreciated by the profession and laity.

(3) Better diagnosis brings intelligent treatment.

(4) Intelligent treatment means the use of combined methods and a thorough working knowledge of the case. This should consist of prophylaxis—better understanding between patient and physician, with attention in the main to social conditions, dietetics, exercise (or rest) as indicated, elimination by proper baths, fresh air, the right cooperative mental attitude, and in some cases climate.

(5) Autointoxication with faulty elimination is directly responsible for these conditions.

(6) That it is necessary for physicians to make a greater study of the toxic effects of leukomains and to lay more on the findings in the urine of the products of indigestion.

(7) An examination of the urine is important in every case for these products of metabolism as well as albumin, casts, and sugar.

(8) Heredity has no effect except as establishing social conditions followed by the family.

(9) The importance of baths and the precedence

of hot mud-packs over other baths for equalizing the circulation, stimulation of glandular activity, and elimination.

(10) The avoidance of a sedentary life and also of great muscular fatigue, the latter being a cause of muscle pains in children and working men.

(11) Alkaline waters and drugs hold a large place as antacids and antiseptics to the intestines, though they are greatly abused.

(12) Hot baths must not be given in dilated hearts, high blood pressure, arteriosclerosis, tuberculosis, and great emaciation, though they are indicated in autointoxication without such complications.

PROGNOSIS IN THE CONSUMPTIVE.*

By J. MOUNT BLEYER, M.D., LL.D., F.R.A.M.S.,

NEW YORK.

The word consumption ordinarily suggests an incurable condition, and one which proceeds slowly yet steadily to its termination, so that there is without doubt in the public mind a greater dread of it than of any other chronic disease in the whole category of illness known to the human family. This is well based upon the facts of the widely-spread cases of the disease, the opportunity which nearly all persons have of tracing its progress from a certain point, and the multitudes who die from it. But on reflection it will be seen that all this may be true, and yet the inference which has been drawn may be unsound, for it only proves that tuberculosis (consumption) is not commonly cured, and not that it is incurable. Indeed, admitting as we do the general truthfulness of the generally received opinions, we feel assured that there are good grounds for believing both the apparently contradictory statements, viz., that tuberculosis is commonly fatal, and yet is commonly curable.

In past years the nature of tuberculosis was not known as it is to-day. We think that there are some reasons for believing that it was not precisely the same then as now. That belief has an excellent foundation when we consider the hygienic conditions in the broadest sense of the times, also, for example, the inflammatory tendency which was common in the seventeenth, eighteenth, and the early part of the nineteenth century, and which is rare now, owing to our modern mode of living; consequently we shall not be justified in adducing former experience either in aid of, or in regard to, the present opinion. But still the most widely-spread source of error is the fact that neither a percentage of the profession nor a great percentage of the public has taken cognizance of the disease in its earliest manifestation, but has admitted its existence only after much advance has been made, and then watching the case from that starting point, it has been seen that the disease is almost universally fatal. If that starting point were the earliest period at which we could become acquainted with the disease, then we would think that the popular belief could not be gainsaid. Hence, the whole question turns upon that point, viz., the general recognition, both by the profession and the public, of the disease in its earliest manifestations. This is the modern trend of the medical world of to-day.

In this view it is easy to admit that the present age is right in believing consumption to be curable in a high percentage of cases, while former ages were equally right in their confirmed belief in the contrary; for, until our improved means of early diagnosis were discovered and widely made known, and cases of the disease were brought together in large numbers for careful investigation and study in the hospital, sanatorium, laboratory, and dead house, it was quite impossible either for the public or the majority of medical practitioners to do otherwise than commence their recognition of the disease at an advanced period of its progress. Then the disease seemed involved in mystery as to its nature, and so hopeless was it in its progress that practically little attempt was made to control it. But now that we have means of tracing conditions preexisting to those which constituted the starting point of former times, we venture to affirm that but few diseases are more clear in their nature, or more readily capable of detection in their very early period of manifestation, than tuberculosis. The modern trained methods employed in recognizing the early stages of tuberculosis should be the study of every practitioner. It is common to speak of the mysterious character of phthisis, as though we assumed that there were other conditions of disease which were more clear, forgetting that we are unacquainted with the essential processes by which either healthy or unhealthy nutrition is carried on, and with the nature of the various conditions of disease to which we have given names. In all these instances we are acquainted with certain leading facts, while the minute changes which they grossly represent are hidden from view; and in like manner, and in various degrees, we possess certain powers by which we may violently arrest the processes upon which the diseased action appears to depend; but in all, our duty is chiefly confined to aiding the efforts of nature. Unquestionably if the want of success which has attended our efforts to arrest the progress of consumption is greater than has attended our efforts to arrest the progress of any other disease, accompanied by an equal destruction of the organ with which it is associated, it is only the great prevalence of the malady, and the vast importance of the organ affected in relation to the animal economy, which has led to the present belief of the special incurability of tuberculosis. It need not be affirmed that we are equally powerless to restore the structure or the function of the liver, or of any other organ on which an equal amount of injury has been inflicted.

Hence we infer that while the present belief may be true under certain existing conditions, the opprobrium which has specially been cast upon the healing art in reference to tuberculosis, is at least in great part most undeserved, and that now, admitting partly the practical incurability of the disease after it has made a certain degree of progress, it is our duty to look at the affection in its earliest aspect, and in doing so to lay aside opinions founded upon facts belonging to a later stage, so that with unprejudiced minds we may ascertain if in that new condition we have not the materials by which the remedial art may act more effectually, and a disease which is in its nature curable.

There is one leading particular in reference to this question in regard to which the present mind is less prejudiced than in former ages. From the days of Hippocrates to those of Laënnec the disease was distinguished by its general symptoms almost exclusively, but Laënnec, introduced the new era, and from that time on the progress of our knowledge has been one grand march forward.

I think that we may with confidence refer to the authorities of the entire medical world adduced as proof of the advance which has been made on this subject within these last few years, and while they

*Read before the American International Congress on Tuberculosis, November 14, 15, and 16, 1906.

may differ as to the exact nature of this pretuberculous (or early stage), they all tend to prove that there is a stage of the disease which exists before that critical period is reached when evidences are to be found, both in the lungs and in the general system, which leave no doubt as to the exact nature of it.

Under what Condition May We Hold Out a Good Prognosis for the Early Stage of the Tuberculous?—It seems almost superfluous or absurd to speak upon prognosis here when we profess to treat a curable disease, but as there are many questions upon which the wished-for issue depends besides the stage of the disease, I think it most convenient to discuss the subject at hand separately.

The conditions in which we may confidently hope for a successful result are the following, especially when they are all present at the same time:

1. The disease in the stage preceding any evidence of a lesion, or when the tuberculous lesion is very small and isolated at the apex of one lung.

2. The progress of the disease has been slow, so that there have been slight evidences of failure of the general system during many months, and with no evidence of a recently accelerated rate.

3. The original state of the constitution was moderately good.

4. The age of the patient is from about twenty years to middle life.

5. The existing state of the health is moderately good, so that, by careful regulation, a due amount of nitrogenous food and of exercise may be taken with comfort.

6. The rates of pulsation and respiration do not vary materially from those in health.

7. Cheerful willingness to obey the prescribed directions, and such pecuniary and domestic circumstances that the whole arrangement necessary to the treatment of the case may be carried out.

8. Due freedom from anxiety, and removal from whatever conditions are unfavorable to the restoration of health.

9. Continuous breathing of fresh air, with all hygienic accompaniments, etc.

Such are the most favorable conditions, and it must further be observed that they are met with in a large proportion of cases in the middle and upper classes of society, but they cannot be universal. As for the poorer classes, the municipalities and the States are taking charge of them and placing them under the best conditions possible to meet these requirements.

The Lungs.—I will now enumerate the several circumstances which are unfavorable, and the degree of importance which should be attached to them, and first the conditions present in the lungs:

1. When the lesion is increased so that it may be detected below the clavicle. The extent of the lesion is important, both because of the interference with the vital functions of the lungs, and by reason of its affording grounds for the occurrence of new complications; but under these conditions there is ground for hope if the amount of the lesion does not appear to be great, so as to interfere much with the circulation of the blood in the parts thus occupied, if the progress has been slow and uniform, and if all the other conditions are favorable. We should attach far greater importance to the limitation of a consolidated or infiltrated mass to a moderate space than to an equal quantity distributed in small masses of infiltration, and yet not spread over a large area.

2. When the deposit is met with in both apices. We think that it cannot admit of a doubt that the progress of the case is greater and the prognosis more unfavorable when there is a small amount of infiltration in both lungs, than when only one lung is implicated in the same, or even in a somewhat greater degree. This would probably imply that the causes of the disease exerted a more general influence, or were more intense, as we should certainly infer that there was double danger of complications; yet, when the deposit is very small, and all other conditions satisfactory, the case is still hopeful.

3. When softening and breaking down of tissue has already taken place. We have limited the curable conditions to those in which the extent of softening is small, and yet involving the whole consolidated mass deposited. Such cases have been seen in which these conditions existed, and every mark of disease has passed away except a certain degree of unevenness of the vesicular murmur over the lesion. We have, however, the conviction that softening in any degree very seriously complicates the case, and it is then only under most favorable circumstances that we can hope for the removal of the softened matter, whether with or without the production of a cavity, which may remain open for a period. In such cases it is impossible to give a favorable prognosis except by watching the progress of the case, but when it is found that the softening is strictly limited, that the evidences of it gradually pass away, that the vesicular murmur is gradually restored by the increased degree of expansion of the surrounding cells, and that no further deposition takes place, a favorable issue may be anticipated.

4. When the feebleness of respiration is very great, so that there is general flattening of the chest wall. It not unfrequently occurs that the degree of diminution of respiratory power and action is very great, without there being any evidences of tuberculous deposit, and in such instances there is marked prostration of the whole nervous system. This is much more common in females than in males, but in both it is particularly found in those who pursue strictly sedentary or indoor occupations, attended by much anxiety and poor living, as for example, seamstresses, tailors, shoemakers, and many such workers.

5. When the patient cannot fully pursue the system of deep respiration, from want either of respiratory power or of appreciation as to the right method of performing it; the causes may also reside in nasal and throat obstructions, etc. I have already here intimated that many such cases are met with in which, with all the training which can be given, the respiratory action is short, quick, and gasping, when an attempt is made to adopt the plan of deep respiration. It is difficult to dissociate the two conditions, but I have no doubt that many persons who have pursued sedentary occupations sedulously for years, and who have lost much courage and nervous power, have also lost the power of easy and deep respiration—in other words, they have forgotten how to breathe. Also those belong in this category who have been born with contracted and deformed chest walls, or who suffer from acquired nasal deformities and many such conditions which interfere with normal breathing, etc. In such instances, the chest falls in respiration below the normal degree, so that there is a less amount of residual air remaining in the lungs, and hence the diminution in the vital processes and the difficulty of maintaining a due degree of expansion of the lungs are proportionally increased. Unless such patients can be taught to respire slowly and deeply, so as to expand the air cells, and also to keep them expanded from time to time, at the end of respiration, we cannot but believe that their condition is hopeless. All deformities hindering the natural respiratory dynamics must be remedied wherever such exist.

6. When hemoptysis is persistent where there is no evidence of progress of the disease or when the disease progresses very slowly. We often run across cases in which the disease appears to be kept in abeyance for two or three years, and the general health is improved, but in which there are, from time to time, attacks of hemoptysis, in those ultimately the signs of progress appear. The importance of this sign is no doubt in the indication it furnishes of the want of freedom of circulation in the lungs as a whole, which attends deficient expansion, or of a depraved state of the blood and general organism, whereby a healthy condition of nutrition is not regained. It occurs without any sign whatever of softening of the tuberculous infiltration which may have been deposited.

The General System.—The following are the unfavorable conditions in the general system which affect the prognosis:

1. When the powers of the general system are greatly enfeebled.

2. When the capability of reaction is found by experience to be very small.

3. When the appetite, digestion, or assimilation is very defective, and particularly when certain kinds of fats, milk, and other kinds of animal food cannot be sufficiently taken, even after careful training.

4. When food, clothing, or proper shelter is deficient in any marked degree.

5. When there is oppressing anxiety.

6. When such a patient cannot be removed from injurious conditions, such as foul or heated air, exposure to cold, and sedentary occupations.

7. When self-abuse or other degenerate practice in either sex is or has been largely practised, or when there are confirmed habits of excessive indulgence in alcoholic liquors or tobacco.

8. When the system is highly sensitive, so that the whole organization is in a state of perpetual unrest, or when it is so deficient in nervous sensibility and activity that it does not respond readily to the ordinary stimuli.

9. When the patient is younger or older than the limits above mentioned.

10. When from any cause the patient will not, or cannot obtain change of climate, providing the case is a typical one for that special treatment, and will not, or cannot steadily pursue the prescribed plan of treatment.

I have not thought it necessary to offer separate comments under these heads, since the whole forms a connected series, and any of them is sufficient to greatly lessen, or perhaps extinguish, hope in the prognosis of the case.

So much importance must be attached to these several questions that I advise the most careful consideration of each one of them, and it is often necessary that the case be watched for a time before a correct judgment can be formed.

As to the importance of age, we may say that in persons aged twelve or fifteen years, or thereabouts, in whom the evidences of tuberculosis exist, we usually find the disease less capable of arrest or cure than in those at a later age. This may be owing to the fact that the early attack of the disease may be in some degree evidence of the deep implication of the system, and probably it may be in part due to complications which arise in reference to the appearance of the menses, and the various rapid changes which occur in the organism and the passions at the period of puberty. But however it may be explained, we augur less favorably of a case in which the disease begins before the age of sixteen than of one in which it is deferred until twenty years of age, or later. The more unfavorable prognosis in advanced age is clearly associated with the progressing defect of the vital powers, the diminution in the expansibility of the lung, which is always progressive at that period, and the diminished possibility of adopting some of the means which are necessary to a cure.

There is one most important relation between the state of the lungs and the general system which we must always consider when forming a prognosis. A small amount of lung disease, with a very enfeebled system, is far more unfavorable than a somewhat larger amount of the former, with a moderately robust state of the latter. While there are many cases in which the general health appears to be moderately good when the lung disease is far advanced, the rule is to find the system injured while the lung disease is yet very limited, and hence, after having ascertained that the latter is restricted within the narrow limits already indicated as hopeful, the whole question of prognosis rests upon the state of the general system.

The Prognosis Based on the General and Numerical Conditions.—Under this heading I purpose to introduce a short summary of facts derived from a very extensive inquiry into the conditions which may be presumed to have modified the constitution of phthisical persons when they were still in health. The primary aspect of this inquiry is that of etiology, and had it been my purpose to have written specially upon the causation of tuberculosis, I should doubtless have referred to the inquiry under that special head. As it has, however, an important bearing upon prognosis in reference to the constitution of the patients, I purpose to insert the results in this place. I do not, however, intend to enter into much detail, but simply to show the direct relation it bears to the prognosis of this disease.

The inquiry embraced an experience of over twenty years. A thousand patients made up this statistical study. Six hundred and twenty-one were males and three hundred and seventy-nine females. I will first consider the circumstances which refer to the parents, and then those belonging to the patients.

Fifty-four per cent. had lost father, 30 per cent. the mother, and 28 per cent. had lost both parents. In 25 per cent. only were both parents living. Their average at death was 50.8 years, with an increased duration of 4.7 years on the part of the fathers. The most frequent age at death was 35 to 55 years, whilst only 11 per cent. died under the age of 35, and some lived to the age of 95. Eighteen per cent. had experienced feeble health before birth of the patient, and 34 per cent. throughout life. In 27 per cent. one or both parents had led unsteady lives. 21.7 per cent. of the parents had died of consumption, whilst in 2.8 per cent. the grandparents, in 23.3 per cent. the brothers or sisters, and in 0.1 per cent. the uncles or aunts had died of the same disease. They had suffered from rheumatism in 22 per cent., from asthma in 0.4 per cent., from liver disease and gout in 9 and 7.2 per cent., and from fevers, cancer, insanity, and diabetes in between 4 and 5 per cent. Presumed scrofulous and syphilitic affections were extremely few and difficult to compute.

The age of the parents at the birth of the patients was, in half of the cases, between 25 and 35 years, and only in 2 per cent. was it less than 20 years. The number of children was very large, viz., an average of 7.5 to a family, and in some families there were twenty-three children. The patient was the first child in 20 per cent., and the first, second, or third child in half of the whole cases; 40 per cent. of the parents' children had died.

Hence, in reference to questions involved in the idea of hereditary predisposition, it has been proved that in a large proportion of the cases the parents died in the middle of life, and had had feeble health. Their children had died in large proportion, and tuberculosis occurred in one-fifth of the parents. But in all these matters there was a large proportion in which there was no evidence of feeble health or direct tendency to tuberculosis. The parents did not marry too early or too late, and the patient was the result neither of immaturity nor of senile exhaustion, so far as age may indicate those conditions, yet he was commonly amongst the earliest children born to the parents. The question of hereditary taint implies either the direct transmission of the disease to the child, or a state of system in which tuberculosis is preeminently liable to occur. The results show that no one condition is dominant.

The average age of the patients at the period of the inquiry was 28.8 years, and 44 per cent. of the whole were between 20 and 30 years of age. In only 13 per cent. were they under the age of 20, and a few were at the age of 60. Twenty per cent. had been feeble at birth, but only 22 per cent. had suffered from feebleness of the general health, and 17 per cent. from generally defective appetite. In 12.6 per cent. the lungs had always been delicate. Only 2.5 per cent. had been dry nursed, 25.4 per cent. had perspired very freely, and 25 per cent. had never worn flannel next the body. Sixteen, 65.4, 60, and 41 per cent. respectively, had not had measles, scarlet fever, smallpox, whooping-cough, or nose and throat affections of various kinds and the frequency of any long-continued ill effects from these diseases was insignificant. Twelve and one-eighth per cent. had suffered from enlarged glands, and 4.5 per cent. from affections of the eyes, but otherwise the evidences of scrofulous diseases existed in a very small per cent. Sixteen and one-seventh per cent. had suffered from acute conditions of the lungs, and 14.8 per cent. from rheumatism, whilst typhoid fever and frequently diarrhea had occurred in 8.0 per cent. Malaria had occurred in 5.6 per cent., and liver disease in 4.3 per cent. of the patients.

Forty and one-fifth per cent. were married, and of these 13 per cent. were up to the period of the inquiry childless. Their average age at the birth of their first child was from 20 to 25 years, and in only 9 per cent. were they under the age of 20. The number of children was one and two in 44 per cent., and one, two, and three in 55 per cent. Thirty-eight per cent. of the children had died, and in 43 per cent. the general state of the health of the children was bad. Abortion had occurred in 40.2 per cent. of the child-bearing married women, and some had suffered eight abortions.

Eleven and one-sixth per cent. had committed sexual excesses, 15.2 per cent. had masturbated, and 22 per cent. had suffered from involuntary emissions. Sixteen per cent. had had syphilis, and 38.5 per cent. gonorrhœa. Twenty-nine and one-sixth per cent. had led a hard life at some period, 24.5 per cent. had drunk to excess, and 48 per cent. had smoked tobacco. Nineteen and one-third per cent. had kept late hours, and 23.2 per cent. had suffered much anxiety. In 70 per cent. there was some complaint as to the injurious influence of their occupations, and of those causes exposure, long hours, dust, and hot rooms, bending, posture, and the inhalation of dust or fumes were complained of in 32.1, 28.6, 13.9, 20, and 15.8 per cent., in their order. Nine per cent. had taken mercury largely, and with iodide of potassium, in one or more ways of administration.

Thus a large proportion of the patients had been born with feeble constitutions, had had feeble and short-lived children, had suffered from the effects of injurious occupations, and had been injured by the anxieties and immoralities of life. They were thus influenced by original and acquired causes of disease; but however important the former might be, it is impossible not to admit that the latter were still more so. They had not suffered from early marriages, and, considering their average age, they had been sufficiently prolific, and no inconsiderable proportion had been sterile.

Hence, again, we cannot but regard tuberculous patients as a very mixed class of persons, and one which derives its causes of disease from a greater variety of diverse conditions, many of which are, however, within their control and preventable. The proportion of those who had suffered from general feeble health and insufficient appetite throughout life was very small, but as they were the judges it may be that their standard of health was low.

One striking feature which I must mention was the greater liability of the female over the male sex to many of the ills to which I have referred. Thus, in reference to the parents, more mothers than fathers had children early, had feeble general health, and had died early. Of the patients, more females than males had mothers who died early, had most relatives who had died of tuberculosis, had parents with one child only, had experienced feeble health and defective appetite through life, had had delicacy of the respiratory tract, were married when very young, had feeble children, had lost most children, had suffered from anxiety, had had measles, scarlet fever, whooping-cough, and other diseases, had not worn flannels, had had a very defective education, were of susceptible temperament, had brown eyes, florid complexions, and fleshy habit, and had suffered from coldness of the extremities, etc. This is most striking evidence of the liability of females to conditions tending to constitutional disease.

We may now ask, in conclusion, in what way are we to regard these inquiries as important in reference to prognosis? It may be fairly replied that whatever conditions will so affect the constitution as to induce a disease will, when the disease exists, be so many reasons against the cure; and hence, in estimating the probability of cure of any disease, it is requisite to weigh well the relative importance of the causes which may have induced it. The first requisite in forming a prognosis in the early or curable stage of tuberculosis is to ascertain the leading conditions to which the disease may have been due, with a view to ascertaining the degree of their influence over the constitution and the probability of their removal, and hence, instead of regarding the cases as belonging to one class of persons, it will be found that they are exceedingly multiform and varied. The first place must doubtless be given to such as originally affected the system, and to the sex; so that in those patients whose parents and relatives have exhibited special marks of disease, or of defective constitution, whether tuberculous or otherwise, and in females, the prognosis must be less favorable. So also we must give the first rank to a defective state of the system of the patient commencing in early life and long continuing, from whatever cause it might have arisen. The importance of the acquired causes of disease must be estimated by their intensity and continuance, as well as by the natural vigor of the constitution and the effect which they had produced upon it. As a whole, their position must be secondary to that of those just referred to; but those which acted before adult life, and which then injured the health, and as sex-

ual excess and masturbation are of prime importance, I am therefore of the opinion that in every case there should be careful inquiry into the circumstances now referred to, and that the probability of cure will rest as much upon this as upon the more minute examination of the lungs, etc., and the impression as to the state of the general system of the patient.

These inquiries of a statistical nature which I here offer are simply to illustrate how many different conditions are at work in the predisposing causes of tuberculosis, and to show that there is not only one cause at fault in the acquiring of this disease, but that there are many. This fact I wish to impress strongly for the sake of the patient who comes for an honest advice, and to whom one may frankly tell these facts. Such a consultation will go far to help relieve his anxiety and gain his confidence for future treatment, when he has comprehended that this disease may have had its origin from one or the other of his environments, etc. The family will also be much relieved by the knowledge of the analysis of the case which has been so explicitly given to them, as well as to the patient who seeks treatment for the disease. After all, it is the duty of every physician to give a clear, comprehensive statement of this disease to every patient. If such a rule was carried out, much good in the prevention and cure of the disease would be the outcome.

816 Lexington Avenue.

A MEDICOLEGAL STUDY OF A MORPHIA-MANIAC.

By T. D. CROTHERS, M.D.,

Hartford, Conn.

Superintendent Walnut Lodge Hospital.

The main facts of this case are these: Dr. J. B. Matthews of Greensboro, N. C., was indicted for the murder of his wife December, 1905, and tried for the crime February, 1906. He was found guilty of murder in the second degree and sentenced to twenty years in prison. He was bailed out pending an appeal to the higher court, taken to a sanatorium and treated for his addiction, and later discharged. He evidently relapsed, went to a low boarding-house, and committed suicide. The facts of his history and crime are as follows: He was born in Durham, N. C., in 1870, of highly respectable parents. As a child he was delicate, nervous, erratic, and impulsive, and was indulged by his parents freely. During his school days he drank beer at times, then whiskey, ran away from home and remained concealed for a few days, then returned. From fourteen to twenty years of age his life was very irregular; at one time a railroad brakeman, then a clerk in a tobacco house, and in a grocery store, then in a drug store, then became a student in pharmacy, finally took up medicine, and graduated from a medical college in Richmond in 1893 with honors.

During his medical studies the death of a young woman, to whom he was engaged, produced depression and a suicidal mania. He wrote letters, bidding good-bye to his parents and friends, giving directions as to the conduct of his funeral, and the distribution of his personal effects, then took a large dose of morphine, and later was found in a comatose state, from which he was resuscitated with great difficulty.

A year after he married, and later entered upon the general practice of medicine. So far as it was known his married life was very happy; he was very attentive to his wife in public, and a little boy, born two years after marriage, seemed greatly to increase the enjoyment of each other's society. The first years of his practice were uneventful, except that at intervals he drank spirits to excess, and was known as a drug taker. The last two or three years it was observed that his wife used morphine and was under its influence at times.

His conduct became more and more eccentric, and he changed his place of residence to a neighboring town, then finally settled in Greensboro. He was recognized as a physician of fair attainments, who might have had a lucrative practice and been popular in the community were it not for his eccentric habits and unreliable business methods, which were evidently due to drug taking. The last year or so he used cocaine at times, which fact was evident from his talkative and excited periods, alternated with stupidity and moroseness. His personal appearance showed great physical changes. His habits were careless and his manners abrupt, and his words and statements were unreliable. Prescriptions given at this time were so unusual and careless as to suggest mental disturbance and indifference. All his friends and associates noted his addiction to morphine and other narcotic drugs, and his wide variations of conduct from profound stupor and indifference to irritability and impulsiveness, and regarded him as unsound and more or less irresponsible. On the night of November 30, 1905, he was seen walking to the railroad depot with his wife, in a very happy state of mind. They both seemed to be enjoying themselves with the familiarity of children.

Next morning, December 1, a friend called at his house and found Mrs. Matthews unconscious and breathing badly. The doctor was also in a state of semistupor, and a neighboring woman was sent for. She recognized the gravity of the case and called in two doctors; they summoned the coroner, who was a physician. Extreme morphine poisoning was recognized, and active measures for restoration were begun promptly.

Injections of strychnine and nitroglycerin were given, together with the galvanic battery, and other means were freely used. The doctor explained that his wife had taken a large quantity of strychnine tablets the night before with suicidal intent, and soon after complained of extreme pain and began to vomit, and for this he had given her a quarter of a grain of morphine every half hour from 11 P. M. until morning. One of the physicians gave an unfavorable prognosis. This seemed to please the doctor, who sent several telegrams announcing the death of his wife, and talked of the disposition of her personal effects in a childish way. Later he appealed to the physicians to certify that his wife had died from heart disease, and thus avoid public scandal. In the course of a couple of hours an improvement took place in the symptoms. The battery giving out at this time, an effort was made to get another one, and the doctor was asked to lend his horse and carriage for this purpose. This he refused in a very childish way, claiming that he needed the horse for another purpose. His conduct was generally suspicious, begging the physicians to leave the room so that he could be alone with his wife. Failing in this, he was detected secretly injecting into the arm of his wife some solution from a hypodermic syringe, which was forcibly taken from him, and he made no complaint or explanation. He seemed to be in a confused state and was constantly smoking cigarettes. In the course of an hour after this event his wife was seized with convulsions and died. The physicians concluded that

was due to poisoning, and that the solution which he had given by the needle was strychnine. The reason that the motive for his strange conduct and repeated efforts to be left alone with his wife was for the purpose of making her case fatal by secretly administering some drug, and, failing in this, he boldly attempted to inject a solution under the cover while on the bed. Later he tried to bribe one of the physicians by offering payment for his services, and to enlist his sympathy by the fact of membership in the secret society.

After the death of his wife he talked freely of the funeral, ate a hearty supper, and went to bed, profoundly indifferent to the circumstances and conditions. When arrested, about midnight, he seemed to have no clear idea that he had committed a crime, but regarded the arrest as a very formal matter, which could be adjusted by his explanations to the sheriff. When taken to the jail he demanded whiskey and morphine, and seemed quite irrational and confused. The coroner, who had forcibly taken the syringe from the doctor immediately after the act of injecting the contents in the arm of his wife, found a large mass of white powder, undissolved in the barrel of the syringe. This he took to a drug store, and, by test, decided that it was strychnine.

This fact and circumstances of the death seemed so clear that the prosecuting attorney did not consider it necessary to have a post-mortem examination. Hence the body was buried without any examination, although the undertaker swore that it did not differ from other bodies, and had no appearance of extreme rigidity. The syringe was kept by the coroner until a few weeks before the trial, when it was taken to the Professor of Chemistry at the State University for analysis. He found the powder remaining in the syringe to be morphine, and without any possible trace of strychnine. In jail it was found necessary to give the prisoner morphine daily, and spirits occasionally, and during the trial the amount was greatly increased. The defence was insanity. It was claimed that the prisoner was a morphiamaniac, and by reason of his drug taking was unable to understand the nature and consequence of his conduct, and that he was in such a confused mental condition as to be unable to reason or act rationally, and that the act of injecting secretly into the arm of his wife some substance was idiotic and unreasonable, and did not have any influence in hastening the death of his wife.

It was assumed that his statements of his wife using a large quantity of strychnine tablets might be true, and that his efforts to prevent its poisonous effect by the continuous doses of morphine from 10 or 11 o'clock at night until the early morning of the next day would naturally result in poisoning and coma. Also that during this time, while using morphine himself, his mental condition would be so confused that such a course would be natural and characteristic of the imbecile conduct of a morphiamaniac. The experts for the defence swore that the prisoner was suffering from morphiamania and dementia, with delusions of paretic nature, and that he was in no way able to act sanely or with full consciousness of what he was doing; also that he was incapable of planning and executing a homicide, requiring reason and judgment as to the consequences and nature of the act. In support of this contention it was claimed that he was mentally defective by inheritance. His grandmother on his father's side was insane during her lifetime, and was said to have killed one of her infant children. On his mother's side one uncle died insane and an aunt had some form of convulsions, for one of which she was treated to death. Another one drowned herself, and a third member of the family committed suicide by jumping into a well. Other members of the family were nervous and erratic. In his early life he was impulsive, irritable, and nervous, was eccentric in conduct and manner. It was evident that he inherited a defective brain and nervous system, with a decided predisposition to some form of insanity. His early use of spirits and irregular life, with an attack of suicidal mania, were unmistakable evidences of this. His continued use of spirits and drugs, first at intervals and latterly continuously, was confirmatory evidence. His drug taking had become so prominent as to attract attention and create doubt among his friends of his mental soundness. All the evidence showed that the relations with his wife were amicable, and that she had used morphine with him, and that probably the comatose condition she was found in on the morning of her death was a repetition of what had occurred many times before, in which both had indulged in this drug up to stupor without any serious results following. There was no evidence of malice or motive on the part of the prisoner to procure the death of his wife. His strange conduct and semistuporous condition showed no degree of sanity, but rather the foolish weakness of a dement. The morphine found in the barrel of the syringe had been thrown in recklessly and then water turned on with a view of dissolving it, and in this condition he had attempted to inject it, with a strong probability that none of the contents was actually forced through the needle. The convulsions following had no probable connection with the injection, even had the substance been strychnine. With the pulse not distinguishable and the respiration reduced to five or six per minute, it was exceedingly doubtful that either strychnine or morphine could have been absorbed, even if injected in large quantities, so as to make any impression on the heart.

The prosecution urged that the convulsions and death were caused by the injection of strychnine and that the prisoner had a motive to put his wife out of the way. It was also urged that in other matters he was treacherous, vindictive, and competent to reason and execute a crime, that his drug taking was for the purpose of covering up the responsibility of the act, and that, while under the influence of some narcotic, he appeared conscious during the efforts to resuscitate his wife, and acted rationally on most matters. It was agreed that he was not a combative or irritable man, but nervous and impulsive, and when under the influence of drugs was demented and stupid in his talk and acts. His present appearance was that of pronounced anemia, with a melancholy, abstract face; his eyes were staring and glassy, his voice was jerky and husky, his conversation was in monosyllables, and his general appearance was that of great indifference and unconcern to the surroundings. His face was unsymmetrical, with a V-shaped palate arch and decayed teeth, and the skin of the face was pallid and tightly drawn. He complained of rheumatism, which was literally neuritis.

The toes and feet were contracted and painful, and reflexes were absent from both legs. His heart was regular, but feeble, the appetite was variable and his sleep broken, except when under the influence of morphine. In conversation his voice would drop down to a whisper as if the thought had escaped his mind. At times he claimed to be very faint and would go out into an anteroom, where injections of morphine could be given him, then return and fall into a drowsy state until the effects were

worn off. For the last two years his drug taking had been noted in his depressed sensory and reasoning faculties, and the impulsive, stupid conduct which showed unsoundness and irresponsibility. The judge charged the jury that the question of the kind of poison used, its quantity, when and how administered, should not be considered in their decision, but only the fact beyond all reasonable doubt, that death followed from the poison, administered by the prisoner, also, that if at the time, by reason of morphine which he himself took, and while under its influence administered the same or other drugs to his wife, and by the effect of the drug which he was suffering from he was unconscious of the character and consequence of his act, he could not be guilty of murder in the first degree. But he could not be excused because of the temporary insanity voluntarily brought on himself, and would be guilty of murder in the second degree. If at the time the prisoner administered morphine, or any other poison to his wife he was under the influence of a similar drug and had no purpose to kill her, but recklessly and carelessly administered it, causing her death, there could be no malice, hence he would not be guilty of murder in the first degree, but it would be manslaughter; and no excuse on account of, and by reason of, his mental condition should be considered. He also charged that no matter how far he was under the influence of morphine, if he had mind enough to be conscious of wrong doing, he was responsible. If his moral perceptions were so blunted as not to be able to distinguish between right and wrong, such voluntary incapacity did not excuse his crime. The confusion of the jury was apparent in the verdict of murder in the second degree, and the trial was another example of the effort to administer justice and maintain the majesty of the law and force twelve men to settle the question of the sanity and responsibility of an evident imbecile. A restatement of the leading facts undisputed make this clear.

1. The heredity history in Matthews' case showed a distinct neurotic taint and predisposition to mental instability, with feeble controlling power. In the ordinary strains and drains of life he was incompetent to live normally, but would most naturally develop some form of neurotic disease, according to the environment and conditions of life.

2. His defective heredity was apparent in the sensitive nervous system of early childhood and erratic conduct, manifest in a suicidal mania at the beginning of manhood. This, with the history of spirit and drug taking, was the natural course of defective organism with faulty culture in bad surroundings, disease would follow with absolute certainty from such conditions.

3. The fact of graduating with honors and becoming a popular physician, making and losing many friends by his erratic conduct and increasing eccentricity, was further evidence of a neuropathic and an unstable, unsound brain.

4. The year before the alleged crime he was notorious for his periods of stupor, depression, and talkative delusional deliriums. He became careless in his dress and disregarded many of the proprieties of life, indicating great physical and mental changes. His untruthfulness, lack of respect for his word, absence of pride of character, and petty efforts to take advantage of others further confirmed the fact of his defective reason and irresponsibility.

5. His relations with his wife gave no indication of any variance or disagreement, and at times in public they exhibited great respect and affection for each other. He was not considered by his friends combative or revengeful, but rather the opposite, hence there could be no motive apparent to dispose of his wife.

6. The comatose condition of his wife on the morning of her death could not be called an unusual event, when both were using morphine. His statement that she tried to commit suicide by taking a large dose of strychnine and that he had given as an antidote continuous doses of morphine every half hour, was a very natural order of events, particularly as he was using it himself. His indifference to the efforts of the physicians in restoring her and his apparent impulse of a lunatic, without consciousness of the consequence and results of his act.

7. The further history of the prisoner in jail and during the trial, in which a degree of nervousness bordering on delirium came on unless he was given morphine in sufficient quantities to make him comcomfortable. His general demented condition, erratic talk, and stupor alternating with apparent sanity, but always followed by general unconsciousness concerning himself and surroundings. After the trial he was taken to a sanatorium and the morphine was gradually withdrawn. He was erratic, unreasonable, had delusions, and was with great difficulty managed. His general health improved and he was finally discharged, restored, but he soon after relapsed, began to use spirits and cocaine, and became very violent and delirious when opposed. He was taken back to the hospital and recovered partially, then went out and in a course of a few days went to a low boarding house and shot himself; evidently he was under the influence of morphine and cocaine at this time. This termination of the case was natural and characteristic and confirmed the diagnosis of insanity and imbecility.

Some of the general conclusions may be stated as follows:

1. It was an error of the authorities to assume that death was caused by strychnine, and not verifying it by post-mortem examination and chemical analysis of the contents of the syringe.

2. It was a still more serious error to assume that Matthews was sane and responsible for his acts, especially in that community where his mental condition was a subject of common observation and talk and his drug taking was acknowledged beyond all question.

3. The apparent motive for injecting into his wife's arm some substance to increase the fatality of her condition would naturally demand his arrest and confinement, but the assumption that this was the sane act of a responsible man was a reflection on the intelligence and judgment of the authorities.

4. Matthews should first have been tried by a commission of lunacy, and his mental condition determined. Then the facts of the possibility of his brain being normal with full power of restraint would have appeared. The question of how far a person could use spirits and morphine and other drugs for years and be capable of planning any act requiring judgment and consistency would be answered. How far such a man could be considered rational and conscious of duty, responsibility, and obligation would be apparent. The delusional condition of such a brain and the delirious reasonings and childish talk and conduct would be natural in such a condition. This trial and verdict should mark the close of the medicolegal efforts to determine the criminality and responsibility of persons who are notoriously degenerate and incompetent by reason of the use of spirits and narcotics. There is certainly something gruesome in the effort to de-

termine degrees of sanity in persons who are notorious spirit and drug takers and whose appearance and conduct attract attention and are prominent to all their associates. The law gains nothing by such farcical efforts to determine crime and the degree of punishment which it merits, and human justice gains nothing by attempting to decide how far incompetent and defective brain culprits are able to control and judge of the results of their acts. In reality the higher consciousness of the community and its intelligence are hurt by the injustice of attempting to adjust wrongs in jury trials on the basis of full responsibility. The attempt to make a jury of twelve men understand the actual condition of the mind and motives of a morphiamaniac and determine how far he could reason and judge of the nature and consequence of his acts is a reversion to the theory and practice of the Middle Ages.

PUBLIC CONTROL OF DISEASE THROUGH A NATIONAL DEPARTMENT OF HEALTH.

By HAROLD W. WRIGHT, M.D.,

ASTORIA, LONG ISLAND.

This subject was recently discussed in a general way by Prof. J. Pease Norton, Professor of Economics at Yale University, in the *Journal of the American Medical Association*, September 29, 1906. I wish to present a few remarks upon this subject from the more personal point of view of a private practitioner of medicine.

In the first place I would speak of some of the disadvantages which result from the present methods of practice and which affect both physician and patient. I think I am correct in saying that there is no thoughtful general practitioner living to-day who, no matter how successful he may be from the world's standpoint, is satisfied with the present-day methods by which he is obliged to pursue his vocation.

We start out in the beginning with the highest ideals; we intend to practise as scientific medicine as is possible without regard to pecuniary reward. These ideals have either come to us naturally or have been instilled in us by our teachers in the medical school. We have been told that the practice of medicine is not a trade but a humanitarian calling, and the most noble calling that has ever existed or will exist. We are taught to feel that the knowledge of having done good work should be sufficient reward for our labors. All this we feel to be true: it appeals to our highest nature and we want to act accordingly.

In our hospital course we give ourselves up entirely to the welfare of our patients, we watch the course of their malady with untiring diligence, and we do so purely from a sense of duty which is in accordance with the unselfish and scientific standard we set for ourselves when we were in the medical school. When we enter upon general practice we confidently expect that we shall be able to continue our work in such a spirit, and so we look forward to our life work with much pleasure and enthusiasm. But what happens to the great majority when they have at last become launched upon "the sea of troubles"? And by the "great majority" I mean those who are obliged to live by the practice of their art and yet want to live up to the ideal standard they have set for themselves. These soon find that expenses are heavy, competition severe, and the readiness or ability of the patient to pay for one's services limited to an unexpected degree. They find that they must see a large number of sick people every day in order to pay expenses and have anything left over. Most patients cannot or will not pay for more than one visit a day, if that. Consequently the doctor cannot afford to give more than a very small portion of the day's time to each individual case, especially if his patients are spread over much territory. The doctor finds that he cannot give the same amount of thought and attention to his patient as he did when a hospital interne; it is both a physical and financial impossibility, and so, perforce, he gets the habit of rushing through his work in the modern strenuous and superficial manner. When he has a little time to think quietly a feeling of dissatisfaction, a vague sense of something wanting will come. And what of the other party, the patient? Does he or she never feel that there is something lacking?

As the years pass the doctor sees men of less skill, less intelligence, and lower standards than his own making "a success"; this adds to his dissatisfaction with things in general, and his fellow-practitioners in particular. He may be at odds with his colleagues on account of some slight misunderstanding or indiscretion on his or their part, some little breach of professional etiquette, which is often contributed to by a thoughtless patient's lack of fidelity or love of gossip. Thus, in many communities, we find little or no harmony and cooperation within the profession; everyone is working for himself, forgetful of the purpose of his calling—to save life and prevent disease.

Another source of worriment and disappointment to many is the lack of hospital facilities; either there is no hospital in the neighborhood or none to which the physician feels he can entrust the care of an operative or difficult medical case.

There is another condition which hinders the true progress of our work, and that is the popular demand for a prescription which will alleviate the symptoms at once, regardless of their cause. This condition is due to the fact that in the past physicians have been either too ignorant or too careless to investigate their cases scientifically, and have yielded to this demand rather than take the trouble to instruct their patients in matters of hygiene.

The popular mind being so uneducated has no respect for such advice unless accompanied by the inevitable prescription which usually makes the greater, if not the only impression. So, in order to "succeed," it happens that we must "bluff." Truly, a most disgusting state of affairs in the light of our youthful ideas! In order to make a living we must cater to the public taste like any tradesman.

These are a few of the disadvantages of the present system. Now, let us suppose the existence of a radically different order of affairs and see if these disadvantages would be overcome and benefits, unattainable at present, be obtained.

First, let us presume the existence of a national bureau of health having subordinate bureaus in every community of about a thousand inhabitants. At the head of these bureaus are physicians who have proved their ability to deal with public health problems; men who are wholly devoted to the greatest good of humanity by the prevention of disease. Those of the central bureau have the right to select their subordinates from successful civil service examinees according to the standing and personal qualifications of the latter. All physicians are therefore licensed only by the central bureau and are in the employ of the same. Then let us suppose all the hospitals under the control of the national de-

partment and that one hospital is supplied for each community or district, containing a certain number of people. The hospitals would be the headquarters of the subdivisions of the health department; they would have a staff of resident visiting physicians and a staff of resident and visiting nurses, all under the authority of the hospital superintendent, who would be a physician also. All of these officials would be appointed by the civil service commission of the national bureau.

Every case of illness would then be reported to the local health bureau by the patient or his relatives; a health officer would be sent to the home to investigate the case and treat it there, or at the hospital, according to circumstances, a nurse being also provided if necessary. The attending physician is responsible to someone above him for the conduct of the case, and he has constantly at his command the counsel of his colleagues and the facilities of a hospital. There would be none of the competition and lack of cooperation that exists among physicians at present, because all would be working together for the good of humanity and not for a fee. The physician in charge of a case would have the right and feel free to visit his patient at any time and study the disease in all its aspects; he would not be subject to popular prejudices and have to cater thereto for fear of his patient deserting him.

Under such a system the medical profession would be invested with such a degree of dignity and authority that its counsel would not only be always sought, but its words of advice would also be considered as words of command, and would carry enough respect to be obeyed. The local health bureaus with their hospitals would be centers of medical education of both the profession and the laity in matters pertaining to personal and public hygiene, the prevention of epidemics, and the care of infants and children.

Under such a system medical inspections of the entire population could be made at periodic intervals. Thus many ailments could be abated or prevented and wrong habits of living corrected; the spread of venereal disease could be checked. Because there is strength in consolidation, many sanitary measures could be enforced which are now impracticable; cities could be made to have pure water, a proper sewage system, clean streets, smokeless and dustless air, and sanitary homes. As Professor Norton suggests, the national health department and subdepartments could be allied in cooperation with the departments of education, labor, commerce, immigration, agriculture, and food inspection and the regulation of the drug and proprietary medicine business. Under such a union what good thing for the public well-being could not be accomplished?

Finally, by reason of the fact that every licensed physician had an assured living, he would be able to devote all his time and thought to his proper work with an interest and energy impossible under present conditions. No fortunes could be made out of our fellows' ills, to be sure, but the kind of men who would enter the profession under a system such as I have indicated would neither desire nor attempt to make capital out of their work.

Now as to the practicability of such a system. Are these ideas, which I know might be much better expressed, visionary and impossible of realization or wrong in principle? I grant that they are visionary in the sense that they cannot be carried out practically at once; but I am looking into the future, and a great many plans for human welfare which were once "visionary" have been realized, and not all of them have been found to be wrong in principle or disastrous in results. It may be argued that such a system would "savor too much of paternalism, it would interfere too much with personal liberty, and would be altogether unAmerican." I do not believe that anything is unAmerican which brings the greatest good to the greatest number of people. There has been no such outcry against the present methods of controlling some of the contagious diseases or against international quarantine. Are not these interferences with personal liberty? But would anyone abolish them on that account? Do they not "savor of paternalism"? Is not the public school system guilty in like manner?

But it may be said that such a system would be impracticable, by reason of the great expenditure necessary for its support. I do not believe that such would be the case because such a system could be supported by a just income tax upon its beneficiaries among whom would be numbered every inhabitant of the country. Furthermore, the individual would not feel the expense involved as much as at present he feels the average yearly doctor's bills, and I have already tried to indicate that he would have his ailments much better attended to, as well as other troubles he knows not of, prevented.

The nucleus for such a system already exists in the Public Health and Marine Hospital Service and in our municipal and State health boards. There are already evidences of the growth of power and influence for good in these organizations which now are separate and noncooperative. How much more good they might accomplish, if united, I have already attempted to show.

Conclusions.—1. Present methods of practice hinder us from pursuing our vocation in the spirit appropriate to it.

2. A national department of health, conducted in the way indicated above, would do away with many of these present hindrances and would give better treatment of, and protection from, disease.

3. There are no insurmountable obstacles in the way of such a system, and there are already indications of a complete public control of disease in the future as manifested in the greater influence being acquired by the Public Health Service at Washington and by our municipal health departments.

Method of Infection of the Amniotic Liquid by the Passage of Bacteria and Toxins Through the Membranes of the Ovum.—Guiseppe Ranieri considers the way in which bacteria and toxins may gain access to the amniotic fluid in cases in which the membranes are intact. The amniotic fluid has some bactericidal action on many germs, but the addition to it of meconium renders it more ready to undergo putrefaction. The author has made experiments on animals to ascertain the method of entrance of the germs and gives us his conclusions. The amniotic sac formed of its three membranes, when all perfect cannot be penetrated by pathogenic bacteria. The amniotic fluid can become infected when the sac is still closed, but not all of the three membranes are perfect. The death or maceration of the fetus brings about, after a time, changes in the membranes, such that it allows the passage of pathogenic organisms. Putrefaction, and infection of an unruptured sac may take place with either a living or a dead fetus. Germs and toxins acting on the membranes produce changes in them, such that the poisons are absorbed by the mother, and she experiences fever and intoxication. Toxins pass through more rapidly than bacteria. Emptying of the uterus puts an end to the dangers of the mother.—*Annali di Ostetricia e Ginecologia.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE

New York, January 19, 1907.

ADVANCED THERAPEUTICS IN A GOVERNOR'S MESSAGE.

IN a recent annual message, characterized by the Chicago papers as of wider scope than ever addressed to a legislature, Governor Deneen of Illinois devotes a larger portion to medical matters than is customary in such documents. "To elevate the public charity service to the level of modern efficiency," Governor Deneen makes many wise recommendations which evidence his broad grasp and intelligent understanding of the humane interest in the subject. It is exceedingly heartening to the medical profession, which has long and persistently labored, despite discouragement and lack of sympathy on the part of statesmen and politicians, to elevate the public medical service, to note the recommendations of this progressive Governor of Illinois. "In discussing the improvement in medical administration and treatment," he writes, "I desire to call attention to the fact that medical and nursing science has advanced by leaps and bounds during the past twenty-five years."

"Drugless treatment, work, recreation, and amusement, are prescribed by physicians just as drugs are prescribed" in the psychopathic institute at Kankakee, Ill., and its branches in each State hospital, "where local clinics are conducted to which physicians are invited. These," writes the governor, "will be used in an effort to learn new things about mental and nervous disorders, and perhaps to discover new remedies which will benefit the whole human family." The governor evidently regards hydrotherapy as one of the latter, inasmuch as he dwells upon it as follows: "For hopeful cases the water treatment, known as hydrotherapy, already has been installed in some of the institutions, and I hope will be extended specially to others. By means of this treatment many incipient and acute cases of insanity are cured, and the patients, instead of becoming lifelong inmates of hospitals, and placing a burden upon the State, return to their homes as productive members of society. The installation of the bath treatment costs from $3,000 to $40,000 for each institution, according to the number of acute curable cases admitted. I heartily favor the extension of the system of treatment to all State hospitals receiving acute cases."

The conclusions of this humane layman's message to his Legislature are doubtless based upon reports of his medical advisers; they verify the published observations of the late George W. Foster, who made the first systematic and extensive observations in the Government (Elizabeth) Hospital at Washington, and of the late Dr. Dent of Ward's Island Hospitals and others who have reported striking results in mental and nervous disorders. If the latter are obtained at Kankakee by "prescribing water," as the Governor says, "just as drugs are prescribed," the question obtrudes itself, Why are medical students not instructed in the prescription of water as in the prescription of drugs? Why does the young physician, as Kussmaul said years ago in his official report on improvements in medical education, feel humiliated when in practice he finds himself displaced by the empiric, because he is less capable in applying hydrotherapy, than in using his hypodermic syringe? In the lectures on therapeutics and in the leading textbooks on Materia Medica and Therapeutics, the application of water in disease receives but scant attention. Indeed it were far better for suffering humanity if hydrotherapy were entirely omitted, for these works do not discuss water as they do drugs, and their description of technique of water application is as faulty as is the rationale, if compared with special works on this subject. The clinical results cannot fail to be disappointing, when based upon faulty teaching, which appears to be reproduced by successive authors. In one of the most popular textbooks, one-half of a page, devoted to the drip sheet, is occupied by an imperfect illustration, and the remainder contains a faulty description of its technique. In a recent work on Prophylaxis and Treatment of Diseases, hydrotherapy is mentioned in the treatment of two-thirds of the diseases discussed, but the methods advocated testify to the otherwise well-informed author's unfamiliarity with the teachings of the men who have made hydrotherapy a life study and practice. These works, written by progressive and otherwise capable teachers, reflect the status of instruction in our schools.

Is it not high time for American medical schools to follow the example of the continental universities and establish chairs, from which the principles of hydrotherapy may be taught, and clinics in which its practice may be learned? It is to be hoped that the example of Columbia University, which inaugurated a course of lectures on hydrotherapy last spring, may be emulated by other progressive medical schools.

THE NAVAL MEDICAL SERVICE.

IN the interesting report, recently issued, of the Surgeon-General of the U. S. Navy for the fiscal year ending June 30, 1906, considerable space is devoted to the consideration of the needs of the Medical Corps. For reasons not far to seek, the naval medical service has never, at least not for many years, been popular among young medical men, the result being that there are always many vacancies in the Corps which it is impossible to fill. These vacancies numbered 44 at the close of the fiscal year in 1906, and this notwithstanding that a medical officer was sent to the leading medical colleges of the East in the spring of last year to address the fourth year students and set before them the advantages of the naval medical service.

The attractions of the service are many. The young man, without ties, who enters the Navy leads

a pleasant life with congenial companions; he has an assured social position; opportunity is afforded him of seeing much of the world, at least of that part of it bordering the sea; he has enough to do to keep him occupied, yet the work is in general not arduous, and while on shore duty ample opportunity is afforded him of prosecuting original research; and finally, his pay, for the early years at least, is greater than he could naturally expect to earn in practice, and he is assured a certain, though moderate, income for life. The disadvantages are that promotion is slow, much slower than in the medical services of the Army or of the Public Health and Marine-Hospital Service; the medical officers of the Navy, unlike his colleagues in the other services, is unable to retire on half pay after thirty years' service; and finally, the naval medical officer, unlike the "Admiral of the Queen's Navie," is obliged to go to sea, and, indeed, to spend much of his life in sea service. To the man who is married, or who hopes to marry, this is a very serious fact. The wife and family cannot go to sea with him. If he is ordered to some definite station, such as the Mediterranean or the Philippines, his family can follow him and take lodgings in some seaport where his ship is likely to be the greater part of the time, and he can see them occasionally. But they may have made the journey at great expense and have just settled down in the foreign city, when orders come for the surgeon to return home or go to some other station at the other end of the world, and then comes another long separation and another tedious and expensive journey for the wife and children. This is the most serious objection to a naval life, whether in the medical corps or the line, and it is one which is inseparable from the service. To the young man with no thought of marrying, it may have little weight, but one who thinks of the future and who is not sure of immunity against the *Bacillus matrimonii* will be apt to hesitate before shutting the door against wedded happiness.

The other disadvantages of the service are not irremediable, and Admiral Rixey makes several recommendations in his report looking to an improvement in these respects. At the present promotion, except to the lower grade of passed assistant surgeon, is practically at a standstill. There will be a yearly average of only three retirements for age for the next twenty-two years, or 63 in all, and deaths and voluntary resignations will not more than double this number. Congress has relieved in a measure the stagnation in the line by providing for voluntary retirement in the grades of captain, commander, and lieutenant-commander in order to create an average number of vacancies in the upper grades, and for retirement by selection in these grades in case the voluntary retirements are not sufficient to cause the required number of vacancies. But the bill providing for promotion in the line did not include the medical corps. In order to remedy this Admiral Rixey recommends an increase in the number of surgeons, medical inspectors, and medical directors, thus creating a corresponding number of vacancies in the lower grades and giving a chance for promotion. He also urges that provision be made for voluntary retirement in the medical corps, such as exists in the Army and Marine Corps and in the line in the Navy. If this were done, promotion would be more rapid, and the young man who enters the medical service of the Navy to-day would not be kept indefinitely in the grade of passed assistant surgeon with no prospect of rising higher until his hair is thin and gray and his heart made sick by deferred hope.

The suggestions of the Surgeon-General are modest enough, and the necessities of the service demand that they should receive recognition by Congress. The disadvantages of the service inseparable from the necessary sea-duty are great and they can be counterbalanced only by making the prizes greater. Instead of being slow, promotion in the Medical Corps of the Navy should be more rapid than in the Army or Marine-Hospital Service, and the pay in the corresponding ranks should be greater than in the other services. It is only by offering greater inducements that those contemplating entering one of the medical services can be attracted to the Navy in sufficient numbers to keep the service up to the necessary point of efficiency.

TUBERCULOSIS AND MILK.

The sensational declaration made by Robert Koch, at the London Tuberculosis Congress a few years ago, that there is no danger to man from the flesh or milk of tuberculous cattle, fortunately never obtained wide credence in English-speaking countries and indeed was speedily discredited in his own country. Nevertheless, the weight of his authority and the extended publicity given to his utterances by the public press tended to allay in a measure the very salutary fear of the consumption of milk from diseased cows. The health authorities never relaxed their efforts to exterminate the disease among dairy herds, but individuals here and there have raised their voices against what they termed the useless sacrifice of valuable cattle, basing their protests on the injudicious statements of Koch. It is well, therefore, that the subject has continued to receive attention at the hands of experimenters here and abroad, until overwhelming proof has been accumulated that Koch was as wrong as wrong can be.

The latest evidence in this direction is contained in a recently published Bulletin of the Bureau of Animal Industry of the U. S. Department of Agriculture. The Bulletin embodies a report of experiments that have been conducted by Dr. E. C. Schroeder and W. E. Cotton of the experiment station of the Bureau of Animal Industry. They have undertaken experiments for the purpose of testing the susceptibility of the lung to infection with tubercle bacilli, and have most conclusively demonstrated that pulmonary tuberculosis may be caused, no matter through what channel the bacilli gain entrance to the body. These experimenters claim, indeed, as a result of their experiments, that the lung is the part most frequently affected, even when the infectious material is ingested with food. They demonstrate that fresh tuberculous material, such as is contained in the milk of diseased cows, induces tuberculosis more quickly and more certainly than the dried bacilli, whether inhaled or ingested with food. A tuberculosis [illegible] than the [illegible] terial from cattle has the highest [illegible] all

tested species of the mammalian kingdom, to which man anatomically and physiologically belongs, and tuberculous material from man has a lower virulence."

The Bulletin concludes that there is "no more active agent than the tuberculous cow for the increase of tuberculosis among animals and its persistence among men." This statement is strong, but it seems to be based upon the results of careful experiments, and if it is not exaggerated its significance can hardly be overestimated when we consider not only the wide consumption of milk by children and adults, in health and disease, but also the fact that milk forms one of the staple articles of diet for the tuberculous.

Defective Death Certificates.

Attention is drawn in the Bulletin of the New York State Department of Health for December, 1906, to the unsatisfactory returns often made by physicians regarding the cause of death. In many cases the physician neglects to supply the information called for regarding the occupation, conjugal conditions, birthplace, and birthplace of the parents of the decedent. This is a seemingly small matter, yet it is of importance as regards the accuracy of the statistics. The most serious defects, however, are in respect of the cause of death. The signer of the certificate often contents himself with a general statement, such as "debility," "inanition," "exhaustion," or "old age," without specifying to what the debility or the exhaustion was due, or noting the disease which caused death in the aged—for unfortunately death from simple slowing down of the vital processes unaided by defect in some vital organ is extremely rare. Other indefinite terms employed are abscess, convulsions, fever, paralysis, spinal disease, heart disease, tumor, etc., no qualification being given as to the location of the abscess or tumor, the nature of the fever, the cause of the convulsions, or the particular disease of the spinal cord or of the heart which existed. The Bulletin states that there has been a marked improvement in these respects in recent years, but there are still many defective certificates returned. With a view to obtaining accuracy in the records of the Department notice is given that all officers designated to receive death certificates and issue burial permits are instructed to refuse to accept any certificate which is defective in the ways above mentioned, which is not written throughout in black ink, which is mutilated or illegible, or in which there is any erasure, interlining, correction, or alteration of anything printed or written on the certificate. Apart from the fact that a properly filled certificate is essential if accurate records are to be kept, it is to the interest of the physician himself to perform this work properly, for the records are open at all times to the public, and are frequently consulted, and some of the returns would be looked upon with shame by the physicians issuing them in case they were made public, as they might be under certain circumstances. If the physician whose unpleasant duty it is to fill out a death certificate always performed his task with care and conscientiousness, he would have the satisfaction of knowing that he had contributed his part to the perfection of the statistical records, and he might also be spared the chagrin of having his unsatisfactory diagnosis made public, or of having the certificate returned to him for correction by the health officer.

Hematocolpos and Hematometra.

It is not the existence of either one or the other of these conditions that is so extremely rare, but their combination is a very unusual clinical fact. A. Deletrez, in the *Annales de Gynécologie et d'Obstétrique* for December, 1906, gives a most interesting account of a case of this nature in which he operated in July, 1906. The patient was a girl eighteen years old, without any hereditary history relating in any way to the anomaly which she presented. Menstruation had never taken place. For four years the patient had suffered pain every month in the hypogastric, iliac, and mammary regions. The pain had been so severe that the patient had been obliged to rest in bed for several days every month during the attack. Within the last three or four months before operation the abdomen had increased distinctly in volume. The pain was almost continuous with periodical exacerbations. The general condition was very satisfactory, micturition was normal, and constipation was habitual. Abdominal palpation determined the existence of a median tumor, globular, slightly movable, and extending up beyond the umbilicus. Examination of the external genitals demonstrated an imperforate vagina, but with no projection of the hymen. The urinary meatus was edematous and varicose. Vesical catheterism indicated that the bladder was directed toward the right. Incision of the hymen did not result in any discharge, but incision of a membrane obstructing the lower third of the vagina was followed by a discharge of about three liters of a viscous chocolate-colored liquid. At the same time the abdomen decreased in size, and the uterus decreased progressively in volume. The opening was dilated by the aid of the fingers, and the operator was able to reach the cervix, which was softened and easily allowed the introduction of the first phalanx of the first finger. Dilatation was practised for several days. The first menstruation was established four weeks after intervention, and since that time this function has been regular. The involution of the uterus was complete. Hematocolpos is almost always congenital. It develops slowly. When hematocolpos extends to the uterus and produces hematometra, the blood may invade the tubes and give rise to a hematosalpinx, or it may overflow into the peritoneal cavity and determine phenomena which are grave, sometimes even resulting in death.

The Technique of Spinal Anesthesia.

While spinal anesthesia does not seem to be altogether justifying the oftentimes extravagant enthusiasm with which it was taken up during the earlier years of its history, many surgeons believe that it has a well-defined province of utility. An interesting observation which if it turns out to be well founded should serve to reduce to a considerable extent the dangers, if not the uncertainties, of the method has been recently published by Hofmann in the *Münchener medizinische Wochenschrift* of December 25, 1906. This operator found that by reducing the amount of anesthetic drug used, but increasing the amount of fluid injected, the area of anesthesia extended much higher than was the case under the ordinary conditions. According to the anesthetic used, the solution is made up in a strength of from [illegible] per cent., with one drop of 1-1000 adrenalin solution to each c.c., and of this solution from 5 to 7 c.c. is injected. The escape of cerebrospinal fluid is prevented as much as possible, and no attempt is made to extend the area of anesthesia by elevating

the pelvis. Hofmann states that by observing this technique the results obtained were more satisfactory than when smaller amounts of fluid containing larger doses of the anesthetic were used, though he admits that occasional failures still occurred. Although he uses the method not infrequently, he believes that spinal anesthesia is usually more satisfactory to the operator than to the patient, particularly if the peritoneum is attacked, and in this connection he relates the experience of a medical man on whom he performed a hernia operation under spinal anesthesia. The manipulations of the hernial sac and stretching of the parietal peritoneum occasioned severe pain, and the patient, who had already on a previous occasion been subjected to anesthesia by inhalation, stated that he should certainly prefer this method in case another operation should ever become necessary.

Milk as a Hemostatic.

The novel suggestion has been made that as milk contains several constituents which are prescribed as remedies in hemorrhage, the substance itself be used for this purpose. Among these ingredients are iron, phosphoric, citric, and sulphuric acids, the lime salts, and albumin. The calcium salts are an important element in coagulation of the blood and the albuminoids have a tendency to increase the fibrinogen. In a recent article in the *Therapeutische Monatshefte*, 1906, No. 10, Solt states how his attention was attracted to the value of milk in this relation. A young girl flowed very profusely during her first menstrual period, and by none of the usual means was it possible to check the hemorrhage. She became comatose and vomited constantly. A nutrient enema was given consisting of milk with only a little salt added and the bleeding ceased. Some years ago Aronsohn reported good success with milk enemas in hemoptysis, and animated by this and his own success the writer continued the use of the agent in a variety of bleeding cases. In a male patient who suffered from severe gastric hemorrhage as the result of ulcer of the stomach, the bleeding was quickly checked by the rectal injection of a liter of milk which was freely salted. In postpartum uterine hemorrhages Solt also employed these milk injections with good results, as well as during the climacteric when every other remedy had failed. It is recommended that the injections be given with the patient on the side so that the fluid can be easily retained, and its temperature should be that of the body. The effect seems to be favored if a bulb syringe is used, as the interrupted stream, particularly in uterine hemorrhage, produces a kind of vibratory pressure on the organ. Solt's suggestion is certainly interesting, and as it can be readily applied, no harm can come from further trials of it.

The Treatment of Tuberculosis.

The Committee on the Prevention of Tuberculosis of the Charity Organization Society points out the great value of the tuberculosis exhibition as a means of educating the people in regard to the prophylaxis and treatment of this disease. Starting with an exhibition held in New York City by the National Association for the Study and Prevention of Tuberculosis and the local committee, there have been held in New York City and other places fourteen tuberculosis exhibitions, which have been visited by 300,000 persons. These exhibitions have been devised to show in a popular way that tuberculosis is a communicable disease, that it is a curable disease, and that it is a preventable disease. This is demonstrated by lectures, by photographs of sanatoria, hospitals, and dispensaries for the treatment and cure of tuberculosis, by many models of tenement houses, sleeping shacks, and "lean-tos," by diagrams and charts showing the prevalence of the disease in the population at large, and especially in certain sections and in certain occupations, by pathological specimens of infected lungs and other organs of the body. The whole subject is presented in such a way as to carry conviction to the layman, and to lead to a realization that effort to stamp out the disease is worth while. An evidence of the popular interest that has been excited in the subject is the fact that at the exhibition held in the tenement districts of New York City there was an attendance of 94,000 persons.

China's Attempted Reform.

In view of their expected losses on the enormous stocks of opium in bond at Shanghai and Hongkong, British merchants are seeking indemnity from the Chinese Government for losses they may sustain under the operation of the new anti-opium law. It is estimated that the export of opium from India amounts to 75,000 chests annually, valued at $38,950,000, and this business will be entirely lost in a few years if the law is strictly enforced. The regulations issued on November 21, 1906, as the result of a decree of the Emperor of China and the Council of State, contain the following provisions: The cultivation of the poppy and the use of opium must cease in ten years. No new ground can be placed under cultivation, and the ground under cultivation now must be reduced one-tenth every year, under penalty of confiscation. All persons who use opium must be registered, and so must the quantity each uses. Only a registered person can buy opium. No one may begin the use of opium after the issuance of the regulations. Shops that sell opium are to be closed gradually. All opium dens are to be closed within six months. The authorities must set the example of discontinuing the use of the drug. Those who find that they cannot discontinue within six months will be deprived of rank and office. Teachers, scholars, soldiers, and sailors are allowed three months in which to discontinue. We should not regard as unduly sceptical one who might doubt the practicability of the enforcement of such a Draconic law as this. It has been the experience of Western nations that legislative prohibition of the sale of alcoholic beverages may restrict, but does not wholly prevent their use or abuse, and it is not likely that greater success will attend China's effort to overcome a national vice in as short a time.

Medical News in the Daily Press.

In the *Journal of the American Medical Association* of January 5 is a letter with the above heading from Mr. C. S. N. Hallberg, a member of the Council on Pharmacy and Chemistry, calling to account two of the Chicago daily papers for their cabled extract of a symposium on influenza, published in the London *Practitioner* for January, 1907. He takes special exception to the statement that Sir William Broadbent found quinine of service, and that his normal prescription was "one drachm of ammoniated quinine and two drachms of liquor ammoniæ acetatis every hour for three hours, and then every four hours." The newspapers were right, however, for

that is the prescription exactly as Sir William Broadbent wrote it, or at least as the *Practitioner* printed it, and the writer's wrath was misdirected. Indeed the newspapers are deserving of praise in this instance for their extreme accuracy, something which is not usually characteristic of press reports of medical matters, and which, being so rare, is worthy of the prominence given to it by the Councilor's premature reprobation. To an Englishman the statement is perfectly intelligible, for of course Sir William meant the ammoniated tincture of quinine of the British Pharmacopœia, which Mr. Hallberg declares to contain "one grain of quinine sulphate to the fluidrachm in diluted alcohol with a little ammonia water." This is not the exact formula, but it is probably as nearly correct as the newspapers would have got it.

News of the Week.

The Society for the Prevention of Unnecessary Noise was organized on Monday of this week at a meeting attended by a number of prominent physicians, hospital superintendents, and others interested in the welfare of the citizens of this town. Mrs. Isaac L. Rice was unanimously elected president of the society and Mr. John J. Rooney secretary. A constitution was adopted and an appeal to the public, setting forth the objects of the society and the need of its existence, was read and approved. Membership in the society is open to all in sympathy with its object. The annual dues for active members are $2, and there is no initiation fee. Other classes of membership are the founders, who pay $100, patrons $50, and life members $25.

The Sewage Disposal Problem.—The United States Geological Survey has just issued, under the title of "Water Supply and Irrigation Paper No. 185," a valuable contribution to the literature on the disposal and purification of sewage. The investigations described in this publication were made at the Sanitary Research Laboratory and Sewage Experiment Station of the Massachusetts Institute of Technology, under the direction of Prof. William T. Sedgwick. The results of this work, and the practical conclusions that have been drawn, are by no means applicable merely to large cities, but contain lessons of practical value to all communities having to deal with the ever-present sewage disposal problem. The description of the experiments is preceded by a historical review of the whole sewage disposal problem, from its origin up to the present time. The paper may be obtained by application to the Director of the Geological Survey, Washington, D. C.

Typhoid Fever.—The number of new cases of typhoid fever in Scranton and vicinity is diminishing, and in three days recently the total number of new cases reported was twenty-five, which is a great improvement. The total number of cases is given as 1,084, with 168 deaths. Pittsburg is also suffering severely from the disease, and there has been a marked increase in the number of cases of typhoid fever in Philadelphia, the majority occurring in sections not yet supplied with filtered water. Two hundred and fifty-two cases were reported for the week ended January 14. There were more than 9,000 cases during the year 1906, with upward of 1,000 deaths.

Food and Drug Inspectors Needed.—The Civil Service Commission has issued notice of a general examination on February 5 for the purpose of obtaining a list of persons qualified for appointment as inspectors and chemists in the Department of Agriculture. The examinations are limited to men, and the salaries range from $2,000 to $3,000 per annum. These positions are made necessary by the large inspection service required by the enforcement of the Pure Food and Drug Act, which went into effect on January 1.

Leprosy in Russia.—The Russian Government is said to be making active efforts to resist the spread of leprosy in the Baltic provinces, where the disease is very common, especially among the Lettish population. As one means of repressing the disease a society for the cure of leprosy has been formed at Dorpat, and sanatoria have been built. Doctors have been sent out to travel through the country to search out persons suffering from the disease, but they have met with great difficulties, as the people refuse to submit to examination or to avail themselves of the facilities offered for treatment. These official investigations, however, have shown what immense strides the disease has made. The number of lepers in Esthonia alone is reported as 5,000, distributed in various areas.

A Lacteal Fluid from Beans.—A Japanese, Dr. Kalayama, is reported to have devised a method for preparing milk-like fluid from soy beans that can be condensed and produced at a far less cost than cow's milk. The bean juice consists of 92.5 per cent. water, 3.02 protein, 2.16 fat, 0.03 fiber, 1.88 other nonnitrogenous substances, and 0.41 ash. To the juice the inventor adds a little sugar and potassium phosphate, and then condenses the mixture. The milk thus prepared is of a yellowish color, and is pleasant to the palate, tasting somewhat like cow's milk, with a slight flavor of soy beans.

The Army Canteen.—A movement intended to aid in the restoration of the army canteen has been started by a number of Washington, D. C., women. They have formed a society to be known as the Army Canteen Club, and have taken steps to form similar clubs in Chicago, Cincinnati, and several places in New York State. These ladies hold that the restoration of the army canteen will be in the interest of genuine practical temperance, and against what they designate as "the mistaken theory of temperance."

Influenza in Baltimore.—According to the estimates of the Baltimore Health Department over 100,000 persons have been affected by the prevalent epidemic of grip in that city.

Scarlet Fever in Boston.—A mild epidemic of scarlet fever is prevalent in Boston and its environs, and in one day recently fifty new cases of the disease were reported to the Board of Health.

The Fenger Memorial Association was incorporated in Chicago on December 26. It is the plan of the association to establish a fund in memory of the late Dr. Christian Fenger, for the purpose of encouraging original research in bacteriology, surgery, and pathology. Annual cash prizes are to be awarded. The incorporators are Drs. Frank Billings, George W. Webster, John B. Murphy, Wm. T. Belfield, Ludwig Hektoen, Carl Doepfner, and Charles S. Bacon.

An Inquiry into the "Poison Squad" Tests.—A resolution has been introduced into the House of Representatives asking the Secretary of Agriculture to inform the House by what authority the food tests by Dr. Wiley, Chief of the Bureau of Chemistry, and his "poison squad" were held. The resolution also seeks to ascertain whether or not these

tests were responsible for the death of a member of the group of young men who ate the experimental food. The physicians who attended the young man have stated that his death was due to pulmonary tuberculosis, but his mother alleges that the disease was induced by the so-called poisoned food. One of the statements made by the mother in her charge is that on one occasion her son let fall one of the capsules to be added to the food he was to take, and there was so much boric acid in it that "it took the paint off the floor!"

Red Cross Aid to China.—Plans are being made by the Red Cross for the regular shipment to China of supplies for the relief of famine sufferers. Three hundred tons of flour have been ordered through the Commissary-General of the Army, and will be shipped to Shanghai.

Premature Senility.—An unusual instance of the untimely inset of senility is reported from Minneapolis, Minn. A boy of eleven years who has just died in the City Hospital is stated to have had organs corresponding in their condition to those ordinarily seen at an advanced age. It is alleged that when the child was six years old his hair began to turn gray, his eyesight began to fail, and he walked with the deliberate care of a person well advanced in years. As a very young child he was exceptionally bright, but his mental faculties had been failing for the last two years.

Cold Cars.—Health Commissioner Whalen, of Chicago has forced the street car officials to comply with the city ordinance requiring that street cars be heated to a certain temperature.

Flat Car Wheels Removed.—The Health Department has announced that since the investigation of the flat car wheel nuisance was begun a few weeks ago, 1,568 such wheels have been removed by the New York City Railway Company.

Dr. Wm. H. Taylor, for forty years obstetrician to the Cincinnati Hospital, has resigned, and been succeeded by Dr. Wm. D. Porter.

Gifts to Hospitals.—By the will of the late Adam Weber, recently filed in the Surrogate's office, the Isabella Heimath is to receive $1,000, and the German Hospital $500. By the will of Louis C. Vanuexem the sum of $25,000 has been devised to Jefferson Hospital of Philadelphia. In accordance with the terms of the will of Miss Harriet Richards, who died at Philadelphia ten years ago, the sum of $5,000 has been donated to St. Joseph's Hospital and to St. Mary's Hospital, for the endowment of free beds. Mr. Bernard M. Baruch has donated $5,000 for a bed in the J. Hood Wright Memorial Hospital, to commemorate his father's long active service to that institution. Dr. Baruch has resigned as attending physician to the hospital, and has been placed on the consulting staff. Mr. Frederick G. Bourne of New York has presented to the Nassau, L. I., Hospital a dispensary and laboratory building, which it is estimated will cost about $10,000. In connection with Mr. Bourne's donation, a Mr. Bird, who formerly lived at Garden City, has presented as a memorial to his wife, Mabel Thorne Bird, $2,000 for an operating room, to be used in connection with the dispensary. A wing on each side of the hospital is now in course of erection, and will be completed March 1. This addition was the gift of Mrs. William K. Vanderbilt, Jr.

Mt. Sinai Hospital.—At the recent meeting of the managers of this hospital Mr. Isaac Wallach resigned the presidency, after having served three years as director, seventeen years as vice-president, and ten years as president of the institution. The secretary's report showed that during the past year 10,543 applicants had been admitted to the hospital. Of these 4,713 were admitted free, 647 were private patients, 249 were private patients in public wards, 622 were paid patients in public wards, while the consultations in the dispensary numbered 158,295 for the year. The total disbursement for the year for the support of the hospital and dispensary was $356,722.63, against receipts of $347,859.84. The deficit of about $9,000 was paid from cash in hand.

The Sixth International Dermatological Congress will be held in this city September 9 to 14, 1907, at the Academy of Medicine. The meetings will be open to the public, and any member of the medical profession in good standing may become a member of the Congress by registering with the Secretary-General at the time of the meeting or previously. The fee for membership is five dollars, payable to the Secretary-General in New York, or to the foreign secretaries. Papers may be presented in writing in the English, French, German, Spanish, or Italian languages, and may be discussed in the language most familiar to the speaker. The Congress will be held under the presidency of Dr. James C. White of Boston, and Dr. John A. Fordyce of 80 West 40th street, New York City, is the Secretary-General. The first Congress of this kind met in Paris in 1880, and since that time at intervals of about three years it has been held in Vienna, London, Paris, and Berlin.

American International Congress on Tuberculosis.—At the session of this organization recently held in this city the following were elected as officers for 1907: *President*, Dr. Clifford H. Irion, New Orleans, La.; *Vice-Presidents*, Dr. Geo. [illegible], Texas, Dr. Thos. Bassett Keys, Chicago, Ill., Dr. Francis T. B. Fast, Las Vegas, N. M., Dr. W. F. Drewry, Petersburg, Va., Dr. I. W. McDonald, Fairmont, W. Va.; *Secretary* and *Treasurer*, Dr. M. M. Smith, Austin, Texas.

Missoula County (Mont.) Medical Society.—At the recent meeting of this society officers were elected as follows: *President*, Dr. E. W. Spottswood; *Vice-President*, Dr. E. F. Dodds; *Secretary-Treasurer*, Dr. H. B. Farnsworth.

New Britain (Conn.) Medical Society.—The following were elected officers by this society at a meeting held on January 1: *President*, Dr. T. G. Wright; *Vice-President*, Dr. S. W. Irving; *Secretary-Treasurer*, Dr. Arvid Anderson.

Muskegon Oceana Counties (Mich.) Medical Association.—Officers were elected as follows at the meeting of this society, held at Muskegon on January 4: *President*, Dr. John F. Denslow; *Vice-President*, Dr. W. W. L. Griffin of Shelby; *Secretary*, Dr. Vernon A. Chapman; *Treasurer*, Dr. Jacob J. Oosting.

Millers River (Mass.) Medical Society.—At the annual meeting of this society, held on January 1, the following officers were elected: *President*, Dr. E. F. Mullins of Baldwinville; *Vice-President*, Dr. A. C. Leach of Orange; *Secretary-Treasurer*, Dr. George L. Perry of Athol.

Etowah (Ala.) Medical Association.—The annual election of officers of this society, held on January 1, resulted as follows: *President*, Dr. E. T. Camp, Gadsden; *Vice-President*, Dr. J. P. Stewart, Attalla; *Secretary*, Dr. Aker Gadsden.

Obituary Notes.—Dr. EDWARD GILMAN BRYANT of this city died on January 8 at the age of thirty-nine years. He was born in Boston, and was a graduate of Harvard University. After serving for a time as physician to the port of Boston he came to this city, and for some years had been connected with the Willard Parker Hospital.

Dr. EDMUND C. RICKERTS of Brooklyn died on January 9 in his fifty-third year. He was graduated from the College of Physicians and Surgeons about twenty years ago.

Dr. SIMON I. GROOT of Washington, D. C., died on January 8 at the age of eighty-nine years. He was one of the founders of the Homeopathic Hospital in Washington, and was one of the oldest practitioners of the city.

Dr. ALFONS MUELER of this city died on January 9 at the age of forty-five years. A few hours before his death he made two visits on patients suffering from pneumonia, although he was himself the victim of the same disease. He was graduated from the University of Halle in 1886.

Dr. PHILIP E. JOHNSON, recently of this city, died suddenly in Portland, Ore., on January 8. Dr. Johnson was graduated from Columbia University in the class of 1892, and had settled in Portland a few months ago.

Dr. E. O. BENNETT of Detroit, Mich., is dead at the age of seventy years. He had served as a surgeon during the Civil War, and for nineteen years was superintendent of the County Asylum at Eloise. He resigned this position in 1900 to become surgeon of the Michigan Soldiers' Home at Grand Rapids, but was forced by failing health to give up active work in 1903.

Dr. H. C. BERGER of Milwaukee, Wis., died suddenly of heart disease on January 2. He was a native of Milwaukee, and had practised in that city since 1891, when he was graduated from Rush Medical College, Chicago.

Dr. JULIUS CESAR LEHARDY of Savannah, Ga., died on January 7 of nephritis, at the age of seventy-six years. He was born in Belgium, and after receiving a classical and scientific education in Brussels and Paris completed his medical studies in the Jefferson Medical College of Philadelphia, from which he was graduated in 1855. He commenced to practise near Rome, Ga., but soon after accepted the chair of chemistry in the Oglethorpe Medical College, Savannah. Dr. Lehardy served as a volunteer surgeon in the confederate army through the Civil War, and had occupied numerous official positions, including the presidency of the Georgia State Medical Society and the medical directorship of the Citizens's Sanitary Association of Savannah, an organization which did much to place the sanitation of the city on its present footing.

Dr. GILBERT L. ROSE of Decatur, Mich., died on January 5, after an illness of five days. He was born in Lakeport County, Ind., in 1853, and received his medical education in the Cincinnati College of Medicine. He had practised in Decatur for thirty-one years.

Dr. WILLIAM H. MYERS of Fort Wayne, Ind., died on January 5 at the age of eighty years. He was a graduate of the Jefferson Medical College of Philadelphia, in the class of 1855, and had practised in northwestern Indiana ever since. He was said to have been the first to perform cesarean section in that part of the State.

Dr. F. A. WAGGONER of Hamilton, Ill., died on January 1 in Boulder, Col., at the age of thirty-five years. He was a graduate of Keokuk Medical College, and had practised for some years in Hamilton.

Dr. W. MURRAY JOHNSTON of Los Angeles, Cal., died on December 29 at an advanced age. Dr. Johnston was a native of Maine, and a graduate of the University of Michigan. He had practised in Kansas and Arizona before removing to Los Angeles seventeen years ago.

Dr. HERMAN STEIN of Chicago died on December 25, at the age of eighty years. He was born in Germany, and received his education at the University of Heidelberg. He came to this country together with Carl Schurz as a political refugee, and for a time practised medicine in Cincinnati, later on settling in St. Louis. During the Civil War he was a major in General Siegel's regiment. Ten years ago he retired from active practice, and went to Chicago.

Dr. GUSTAVE A. BACHMAN died at Philadelphia on January 8, at the age of sixty-four years. He was graduated from Jefferson Medical College in the class of 1874.

Dr. BENJAMIN PITT JOHNSON, surgeon of the Cunarder *Coronia* died at Liverpool on December 30, of pneumonia, at the age of forty-five years. Dr. Johnson had been in the service of the company for sixteen years, and had been surgeon of the *Umbria*, *Etruria*, and *Coronia*. He was a native of Ludlow, England.

Dr. DANIEL S. ADAMS of Manchester, N. H., died on January 11 at the age of sixty years. He was born in Lockport, N. Y., and had practised in Manchester since 1872. He was at one time president of the New Hampshire Medical Society.

Correspondence.

TRYPSIN FOR THE CURE OF CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Dr. E. W. Peet, in your last issue, under the above caption, lays stress upon the value of "facts" insofar as relates to a preceding article of mine, also published by you under the same title. Regretfully, I feel forced to make answer to this communication, for I well know that, unanswered, misapprehensions and trivialities grow to larger proportions. It seems to me also that a personal attack of this nature is entirely uncalled for.

As to facts in which I am alleged to have been remiss, the first is that Dr. Peet referred a certain case to me. This statement was indeed an inadvertence on my part. I was misled by the fact that Dr. Peet met the patient twice at my office during her early visits, and I believed, therefore, that she was acting with his approval. Hence, as a matter of professional courtesy, I mentioned his name.

As to Dr. Peet's second fact, namely, that he had closely attended the patient at her home during the seven weeks she had been under treatment by *x*-ray given by me; that he had made "very careful and frequent notes of the case;" that his "notes do not at all agree with the report made by Dr. Morton in his article," which latter as regards the results of *x*-ray reported in Case I. is further termed "optimistic," "beyond comprehension, etc., etc., I submit the following letter, written to me by the patient:

"New York, Jan. 15, 1907. Dear Dr. Morton: In reference to the statement of Dr. E. W. Peet, published in the MEDICAL RECORD of January 12, 1907, where he says, 'I continued to attend the patient at her home and made very careful and frequent notes of the progress of the case while she was under treatment,' and further says 'that at all times during these seven weeks I was able to make out enlarged axillary glands and detect lymphatic infection by palpation.' I think it my duty to say to you that at no time during the seven weeks referred to was I aware that Dr. Peet was in attendance upon me at my home or elsewhere, nor do I know of a single instance during that time when he examined me, except on two occasions when, at his own instance, he came to your office when I first was being treated. As a matter of fact, the late President Harper of Chicago University introduced me to you and advised me to take treatment with you. I left my case with you unreservedly. In justice to you I make this simple statement. Believe me, most cordially yours, K. H." The patient's full name is signed to the above letter with her permission to use it, but I have preferred to use her initials as in Case I. of my report

Under the above circumstances, I can hardly see how Dr. Peet arrived at his third fact, namely, that my report of the progress of the case during the seven weeks of *x*-ray treatment was optimistic or otherwise, since according to the patient's statement, supplemented I may add by her mother's, he did not "attend the patient at her home," and did not examine her during this time, except at my office, and in the early stage of treatment. The opportunity for making these careful notes of the results of the *x* ray treatment would seem to have been wanting. The *x*-ray treatment, by the way, was merely mentioned by me in my original article as a part of the remote history of the case. And, as a matter of fact, what bearing has Dr. Peet's criticism upon "trypsin for the cure of cancer?"

WILLIAM J. MORTON, M.D.

A METHOD OF OPERATION ON THE LIP.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of November 3, 1906, there is an article with the above title, by C. F. Buckley, M.D., of Brooklyn. Although the author does not distinctly claim this to be a new method, it is rather inferred. I trespass upon your time and space to say that I have used the method to control hemorrhage as well as to increase the effect of local anesthesia.

In operating for the removal of an epithelioma of the lip, at the suggestion of my colleague, Dr. J. Herbert Claiborne, I applied two artery forceps at a suitable distance from the proposed lines of incision, to prevent hemorrhage from the coronary arteries, which it most effectually did. This patient was under general anesthesia, and the method, therefore, only had to do with the use of the forceps as a hemostatic.

Now, as to the application of the clamp before the injection of cocaine—this I myself did long ago in an operation for the removal of an epithelioma of the auricle, which I reported to the New York Medical Society. I, however, never made any claim for originality in this connection. The credit for discovering the method belongs to Dr. J. Leonard Corning (Transactions of the Medical Society of the State of New York, 1887, p. 94).

Dr. Buckley says the necessity under which he once was, "of operating entirely alone on a growth involving the lower lip, was the originator of this idea, which has been used successfully since that time." My object is to show that, although the idea was to him original, practically the same method has been employed before.

THOS. R. POOLEY, M.D.

107 MADISON AVENUE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CHRISTMAS AT THE HOSPITALS—SURGICAL TREATMENT OF NONMALIGNANT GASTRIC ULCERATION—OBITUARY.

LONDON, December 28, 1906.

CHRISTMAS day this year was, so far as weather goes, the most enjoyable for a long period past. Some hours of sunshine, a very slight touch of frost, and very moderate breeze made getting about a pleasure to healthy people. The next day London woke up to a complete transformation; a mantle of snow four to six inches deep covered the ground and impeded locomotion. There was, in fact, hardly any traffic for the first half of the day. The local authorities had been caught napping, and even such quarters as Westminster and Kensington were unprepared, and the snow enforced a rest on horses and men, and with it a delightful silence, as if far from the maddening noise of traffic.

All the hospitals observe Xmas day. There was extra fare for those able to partake, amusements and visits of friends, and all sorts of efforts to cheer sufferers. The children's wards, like the others, were decorated, but the Christmas trees and bountiful distribution of toys were the chief attractions of the little invalids. The supply was unusually large. In many cases the gifts came from one or two generous benefactors; in others there was a subscription among the supporters of the hospital. The decoration of the wards has become a rather expensive feature of the season, and is often done largely at the cost of students and nurses. In some cases this is becoming oppressive, and attempts to restrain the ardor of contributors have been made. This seems especially desirable considering that the work of decorating is mostly done by the same persons.

The surgical treatment of gastric ulcer has occupied the attention of the profession for some time, and it was therefore deemed desirable to hold a full dress debate on it at the Royal Medical and Chirurgical Society. This was opened in November, and has extended over three meetings. Eminent physicians and surgeons stated their opinions and reviewed their experience, and, on the whole, the debate gives the impression of a symposium rather than a discussion. The subject was wide, perhaps too wide, for it was put as the "operative treatment of non-malignant ulcer of the stomach and its complications." Each speaker could, accordingly, deal with the point he felt most interest in, and there was not much opportunity of coming to close grips with divergent views. Nevertheless, the expression of diverse opinions is of no little interest, and a comparison of them will be made by the general practitioner on whom so much responsibility rests for early treatment. There is a general consensus of opinion that perforation calls for immediate operation. But then the question arises as to whether the surgeon should stay his hand when he has closed the opening, or proceed to a further operation. The danger of a second perforation is diminished by a gastroenterostomy which favors the healing of the ulcer and line of sutures, and diminishes the risk of hematemesis. Then arises the question of the patient's condition. Is he able to bear the additional operation? To this one speaker seemed to think the worse he might be the greater the demand for gastroenterostomy, while it offered the only chance in the presence of some complications, e.g., cicatricial stenosis of the pylorus. As to hemorrhage, there is a general agreement that operation should not be performed during an acute attack, which is rarely fatal, not 5 per cent. dying during the hemorrhage. On the other hand, the fatality rises to 60 or 70 per cent. for operation during such attack. This is doubtless because in so many cases the bleeding comes from erosion of the mucous membrane, which in itself has not a high mortality, though the risk of operation is enormous and the chance of benefit slight. The advance of surgery has so greatly diminished its risks that we have become accustomed to statistics which would formerly have been incredible. Mr. Mayo Robson has achieved a mortality of 2 per cent. in early cases of gastric ulcer, and 3 per cent. is not considered unusual. These figures contrast well with the death rate of former hospital admissions; but statistics as to these are very unequal, showing that the conditions must have been very variable. Dr. Hawkins stated that of 550 consecutive cases admitted to St. Thomas' Hospital, the deaths were 13 per cent. Of these 400 were admitted early, and discharged cured, but about 25 per cent. of them relapsed. It was among relapsed cases that nearly all the deaths occurred. The foregoing figures were submitted at the first adjourned meeting. At the next adjournment another series was brought forward by Dr. H. S. French, which may be compared with them, though the conditions were different. At Guy's Hospital up to 1905 only 47 gastrojejunostomies for nonmalignant gastric disease had been performed, and of these 13 were fatal. Excluding 2 cases in which hematemesis was the cause, the mortality was still very high—over 23 per cent. This was partly due to the fact that all had ulcers or their results, and the health of all was very low at the time of operation. These statistics, Dr. French admitted, overstated the risk of gastrojejunostomy, but he did not agree that it was slight in cases of cicatricial stenosis of the pylorus. Of the cases that recovered, 32 per cent. obtained no lasting relief from the operation. As to the after-history of patients who had recovered after operations in Guy's Hospital for perforated ulcers, he found that 30 had recovered, 18 for periods varying between two and eight years, 15 without the recurrence of any gastric symptoms. The other 3 had done badly. In none of these 18 was the gastrojejunostomy done at the time of suturing the ulcer. Mr. Mayo Robson thought these statistics quite dreadful, for there was a failure to relieve symptoms of 32 per cent., with a mortality of 27 per cent. If we had no other statistics we should all leave the meeting saying that patients should no longer be submitted to operation.

The difficulty of drawing conclusions from so prolonged a discussion, ranging over so wide an area, will be understood by every reader, and the general practitioner will perhaps be inclined to fall back on his previous routine, modified by whatever he finds to be an advance distinctly shown. He will say that many cases recover under prolonged rest in bed and strict diet, so that grave operations are not to be risked in most cases, or by other than highly-skilled surgeons, time being in favor of medical treatment. Rectal feeding may give absolute rest to the stomach for a short time, but is admitted to be an inadequate diet for long, and even hematemesis need not prevent nutriment being given by mouth. Six weeks' absolute rest on milk diet, followed by a like period of comparative rest, and that by a further three months careful dieting, was recommended by Mr. Paterson in his Hunterian lectures. If then the patient were not free from definite symptoms, or after an apparent cure had a relapse, he considered an operation was in the best interest of the patients. Out of 143 gastrojejunostomies he found the after-history showed

complete [illegible] 82 per cent. [illegible] operation had been so successful that there was danger of its becoming a fashionable panacea for vague stomach disorders, and so bringing discredit on a most successful treatment in suitable cases. This is an important lesson from the discussion. Another was emphasized by Dr White's warning that when there seemed great danger of death from hemorrhage it should not be said something must be done, for operation might further shorten the short time the patient might survive if left alone.

The death of Dr. William Travers removes a prominent physician from Kensington, in which he had practised since 1866. At first he was a general practitioner, but he attained the position of a consultant among his colleagues of the district. He was physician to the Chelsea Hospital from 1883 to 1894. His health had been failing for some time, but his death was unexpected. He was F.R.C.S., 1864, and M.D. Dub., 1879, and a member of several societies.

Dr. Alfred Sheen, consulting surgeon to the Cardiff Infirmary, died on the 16th inst., in his sixty-eighth year. He studied at Madras College and then at Guy's Hospital, took M. D. Hand., 1862, and M.R.C.S., 1863, D.P.H. Camb., 1888. He wrote "The Workhouse and Its Medical Officer," and was widely known as the author of the "Handy Visiting List and Medical Bookkeeping." In 1880 he contributed to the *Lancet* "Five Years' Surgical Work in Cardiff Infirmary." He leaves a wife and eleven children. His eldest son is a consulting surgeon at Cardiff.

Dr. James Gray, A.M., M.B., etc., of Dundee was found dead in his bed on the 7th inst. He was in his usual health on retiring at night and had visited his patients during the previous day, on which also he had been reappointed assistant surgeon to the Dundee Infirmary. He was assistant professor of surgery at the college and only thirty-four years old.

Deputy Inspector General of Hospitals and Flects R. W. Beaumont died on the 21st inst., aged seventy-eight. He had seen much service and received official recognition of his valuable work with regard to epidemics and disease. He also had the medal for duty well done in the Kaffir war, 1850-2. In 1878 he was senior medical officer in the flagship at the occupation of Cyprus.

OUR LETTER FROM PERU

From Our Special Correspondent.

THE PLAGUE—INFLUENZA—DYSENTERY AND ABSCESS OF THE LIVER—A POISONOUS LIZARD.

AREQUIPA, PERU, November 17, 1906.

There has been no case of bubonic plague in our part of Mollendo for at least six months. Last year it reappeared in the hot months of December, January, and February. In Lima, during the whole year, there have been cases, but, strange to say, the disease has never become epidemic.

August and September may be said to be the months when there is most sickness, especially pneumonia. This year the unhealthy season has been prolonged into October. There have been many cases of influenza, some longer than usual, and a few accompanied by pains in one or more bony prominences of a joint or joints, these pains disappearing slowly.

In one of your Philippine letters your correspondent says that the doctors there find that all cases of abscess of the liver have been preceded by dysentery. That is not our experience, and I see that Dr. Advrozola, a prominent physician of Lima, in a short lecture published in the *Crónica Médica* of that town, says that he has not found that to be invariably the case.

There is a small lizard here and on the coast which is popularly looked upon with great dread. They call it "salamanqueja" (corruption of salamandra?), length, 12 centimeters. So far as I can see, in a preserved specimen, the only difference between it and the common lizards is that the "salamanqueja" has clubbed digits. On the coast it gets the credit of being able to cause death. Here I have never seen such a result. True, most venomous animals are more venomous on the coast than in colder regions. My experience of the effects attributed to the bite is confined to a few cases; but they were all similar. The patient feels as if stung by a wasp. He rubs the part a little and the feeling passes off. I have never seen a case where the animal was caught in the act; it has been found (or not found) later—perhaps next day—in the room. Supposing the bite to have been received in the middle of the day, at night the patient feels an itchy and then a painful burning. There generally are shivering and then fever. I have even seen urticaria. The constitutional symptoms pass off in a few days, but the local affection extends, with itchy, burning, swelling and dusky redness, to about the size of the palm of an ordinary hand. At last a line of demarcation appears. The whole sphacelates, skin, subcutaneous, and adipose tissue exposing the muscles. The wound heals kindly.

Progress of Medical Science.

New York Medical Journal, January 5, 1907.

The Treatment of Tuberculous Glands of the Neck by the X-ray.—Histories of two cases are given by G. S. Leidstein whose conclusions on the general subject are as follows: (1) Such glands should be subjected to x-ray therapy when no softening or caseation has taken place; (2) softening or cascous glands should be referred to the surgeon, and ought not to have x-ray treatment; (3) postoperative x-ray treatment is important if there is any doubt of remaining glands which might be infected; (4) for cosmetic reasons; (5) the size of the gland or glands does not influence the successful result of the treatment.

Formaldehyde in the Disinfection of Rooms.—The paper of M. J. Rosenau is an affirmation of the validity of the work done in this direction by one of the government services. Experiments were conducted in a zinc-lined room. The general conclusion is that considerable volumes of formaldehyde gas are not sufficient to destroy bacteria unless the proper conditions of moisture and temperature are present. The author declares that much of the work upon the germicidal action of formaldehyde gas is contradictory. We know that the usual source of error is that the cultures exposed are sometimes moist and sometimes dry. Moist cultures may be killed with dry formaldehyde gas. But the dry gas does not kill dry cultures. In a general way it may be said that the most serious limitations to the use of formaldehyde gas as a disinfectant are temperature and moisture. The gas cannot be depended on in cold or dry weather. When the temperature is below 60° F., and the relative humidity of the atmosphere is below 65 per cent., the gas frequently fails to kill nonspore bearing organisms.

Albuminuria of Prostatic and Seminal Origin with Reports of Two Cases.—W. G. Young reports two cases. This form of albuminuria seems to occur in cases of prostatic congestion, and mild inflammation in both continent men and men of irregular sexual life. Habitual sexual excitement without gratification is an important factor in bringing about the prostatic and vesicular condition responsible for the albuminuria. Constipation is also a factor in causing and keeping up the condition. The prostates in these cases are found to be tender, slightly enlarged, soft, and edematous. The vesicles are usually tender, often distended, and the posterior urethra very sensitive. An interesting feature in these cases is the fact that the albuminuria is intermittent. It was noted in the author's cases that it was sometimes absent in the morning, but present the same afternoon. The prostate and vesicles are in a relaxed and atonic condition, and the exercise of the day's going about may act like massage, squeezing out their contents into the posterior urethra and bladder. The patient passes his urine in two glasses, but not entirely emptying the bladder. The first two specimens may be clear, or they may show a slight cloudiness, not referable to phosphates or to pus. The prostate and vesicles are then palpated per rectum, and their contents expressed. In these cases the expressed fluid is often sufficient to appear at the meatus. The remainder of the urine is then passed, and is found to be turbid, and often to contain bluish white, translucent, tapioca-like bodies. This urine will be found to give a much more marked reaction for albumin than that passed before massage. The source of the albumin may be the semen or prostatic fluid altered by a transudation into it of serum from the blood, possibly both. The author does not believe that normal prostatic fluid alone when mixed with the urine would give the reaction for albumin. The albumin usually found in the urine after massaging the prostate and vesicles is probably due to the semen expressed during the massage. There is no question but that semen, even in small quantities, mixed with absolutely normal urine, will give positive reactions for albumin.

Journal of the American Medical Association, January 12, 1907.

Endothelioma of the Skin.—W. S. Gottheil, says that it is now the general opinion of pathologists that to the class of endotheliomata belong many of the atypical or mixed new growths called endothelial carcinoma, endothelial sarcoma, angiosarcoma, etc. Their differentiation from cancer and sarcoma is important, as these endotheliomata are essentially benign, slow in growth, without tendency to metastasis or to lymphatic gland involvement, and are not prone to recur after removal. Recorded cases of endotheliomata of the skin are rare,

and their clinical characteristics are not well defined. As yet a positive diagnosis can be made only with the aid of the microscope. Most of the cases have appeared on the scalp as single or multiple, flat or pedunculated tumors. They are not likely to break down, but are very liable to undergo degeneration, more especially of the fatty type, and so to show a more or less marked yellow color; their growth is slow, and they show no evidence of malignancy.

Trypanosomes.—F. G. Novy describes the trypanosomes, gives what is known of their life history, and transmission through insects, etc., and describes the diseases they produce. He does not accept Koch's views of the specific unity of many of the pathogenic trypanosomes, but recognizes eight pathogenic species for mammals, including the kala azar organism, the generic relations of which seem to be somewhat in doubt. Only two of these are pathogenic for human species, the *Tr. gambiensis*, which causes the African sleeping sickness, and the *Tr.? (Piroplasma) donovani*, responsible for the kala azar disease of India, but these are formidable enough. The most formidable trypanosome infection of the domestic animals, the tsetse fly disease of South Africa, has become a much less serious matter since the extermination of most of the wild game of that region that harbored the parasite, the fly itself being only the passive carrier of germs. It is probable also, in Novy's opinion, that the same is true of the *Glossina palpalis*, the biting fly that transmits the germ of sleeping sickness which has lately depopulated whole regions of Eastern Africa. The treatment of the severer forms of trypanosome disease, including those affecting man, is very unsatisfactory. Encouraging results, however, have been obtained with aniline dyes and arsenic in monkeys affected with sleeping sickness, though, save in one case reported by Dutton and Todd, treatment has been ineffectual so far in the human species.

Fractures of the Neck and Shaft of the Femur.—F. E. Peckham describes at length the method of using a modified Thomas splint for treatment of fractures of the shaft of the femur according to the method devised by Ridlon. He makes a special point of frequent measurements under the straps in order to insure the proper length of the leg throughout the treatment, and also of properly supporting the lower end of the leg between the end of the splint and the ankle by a smooth pad. He has used this method in a number of cases with excellent results. In some cases, however, it became necessary to take additional measures to render the limb immovable when constant daily attention could not be given, and he describes a method adopted by him of fitting a plaster cast and windlass attachment during etherization, and illustrates it with cuts. It has, of course, the disadvantage of rendering the surface of the leg inaccessible in part, and therefore some excoriations cannot be avoided, whereas with the Thomas-Ridlon splint every part of the skin can be reached. In fracture of the upper third of the shaft, shortening is almost unavoidable except with children with whom it is also the rule. He treats these cases also with the plaster frame and windlass attachment described. He summarizes as follows: (1) Find out as accurately as may be and with *x*-ray, if possible, exactly what the condition is. Portable *x*-ray outfits now permit radiographs at the bedside, so that fractured necks and shafts may be accurately studied in this way; (2) reduce the fracture under ether and apply the Thomas splint in fractures of the neck and plaster-of-Paris in case of fractured shaft; (3) practise eternal vigilance all through the bed treatment to prevent pressure sores or any other trouble from arising; (4) operate immediately in all cases of nonunion.

The Quinine Treatment of Pneumonia.—M. A. B. Smith testifies to the value of quinine in the treatment of pneumonia, reporting four cases in which it was successfully employed. He believes that in the large doses advocated by Galbraith quinine acts as a specific, as much so as antitoxin in diphtheria. He found that large doses of the drug were better borne by pneumonia patients than small ones, and thinks he might safely have given still larger ones than those of from thirty to fifty grains, which he employed. There were more symptoms of quininism with from six to ten-gram doses than with the larger ones.

X-ray and Radium Treatment of Deep-Seated Cancer.—J. Rudis-Jicinsky reports three cases of inoperable abdominal cancer treated with the *x*-ray, and *x*-ray and radium, with apparent benefit. One patient was apparently well three years after first being seen, and in another the disease seems arrested after a year's treatment. The other patient, though temporarily benefited, died from a recurrence and auto-intoxication over three years after being first seen. Two other cases are mentioned in which the growth disappeared under the treatment, but the patients died later from recurrences. He thinks the facts show that in these cases we must not delay our operative procedures, but, if possible, should make an exploratory incision to ascertain the state of things in every inoperable and deep-seated case, and then ray the growth as soon as possible to prevent suffering and local or general recurrence. In primary operable malignant tumors it is well perhaps to ray the field about ten days before operation, and after operating, ray it again at once to prevent recurrence or infiltration into the glandular tissue, especially in carcinoma and sarcoma. An area three or four inches larger than that of the original tumor is exposed by him to a hard tube; in fact, the harder and deeper the lesion the harder should be the tube.

The Lancet, December 29, 1906.

The Treatment of General Peritonitis.—A. W. Mayo Robson gives a general review of the attitude taken by surgeons relative to the proper treatment of this condition, tracing the question from the time of merely expectant measures up to its present day operative status. He refers to various papers by different men on both sides of the Atlantic and presents some suggestive statistics. The cases thus collated he divides into four groups, as follows: Group 1. Acute appendicitis without perforation, 20 cases with immediate operation and a mortality rate of two and one half per cent., 55 cases with delay in operation, no mortality. Group 2. Acute appendicitis perforated or gangrenous without abscess, 21 immediate, no mortality; 34 with delay, no mortality. Group 3. Acute appendicitis with peritonitis and abscess, 38 immediate, mortality two and one half per cent., 78 with delay, and the same mortality. Group 4. Acute appendicitis with diffuse peritonitis, 33, all with delay in operating, and a mortality of thirty per cent. Concerning the position taken by Ochsner, he states that if we compare the figures here given with the results of the extensive operation involving manipulation of the abdominal contents or evisceration, we cannot but pronounce in favor of Ochsner's treatment, as carried out by himself, which is, moreover, undoubtedly the best treatment in the absence of the possibility of skilled surgery, if it can be carried out thoroughly in every detail as advocated and practised by its author. If, however, we compare the results of *delay*, even in Ochsner's hands in this class of cases, with those of less severe operations, the author thinks we shall be driven to the conclusion that where efficient surgical help and nursing are available immediate operation in spreading or general peritonitis due to appendicitis is likely to yield better results than can be obtained by delay. Moreover, Robson notes the difficulty in making a diagnosis as to the cause of the peritonitis. No one counsels delay in a case of undoubted gastrointestinal perforation or bowel strangulation, but in 52 cases, shown at operation to be due to perforated duodenal ulcer, a correct diagnosis had been made in only 2. Acute pancreatitis may also simulate perforative appendicitis, and delay in such cases certainly would be disastrous. A similar observation applies to perforated gastric ulcer and typhoid perforations. As to the latter Robson declares that it is quite clear that an extensive operation can never be borne and that a rapid repair of the cause and drainage will yield the best results. In the after-treatment the administration per rectum of large quantities of saline fluid with which liquid peptonoids and some diffusible stimulants are mixed is most useful, and if needful it may be supplemented by subcutaneous or intravenous saline infusion. Feeding by the bowel may be supplemented by the subcutaneous administration of a five per cent. glucose solution or by the administration of sterile olive oil subcutaneously until the stomach is capable of retaining nourishment. Liquor strychninæ in five-minim doses subcutaneously every four hours is most useful in combating shock and strengthening the heart. After removal or repair of the cause of the peritonitis one-eighth of a grain of calomel given every hour or two by the mouth until a grain has been administered not only helps the passage onwards of flatus, but by its antiseptic effect tends to prevent decomposition in the gastrointestinal contents and so to arrest the formation of gas; if necessary a turpentine enema is given to assist the expulsion of flatus from the large intestine. If there is distention of the upper abdomen with inefficient vomiting, or if vomiting is persisting, gastric lavage is resorted to and, if needful, repeated from time to time, a method of treatment that often gives great relief.

Cyanosis, General and Local.—Under this heading T. Oliver discusses enteric cyanosis, that of intestinal

Raynaud's workers and really gangrenous, or Raynaud's disease. The first variety frequently occurs in those who regularly take, on their own responsibility, the various modern headache and other powders containing acetanilid and similar compounds. Some cases have been found due to intestinal organisms which possess the power of influencing blood composition. Workers in marble become markedly cyanosed and pass dark colored urine. In man the poison may enter by the skin, by the alimentary canal, or by the respiratory organs, and the symptoms are always the same—viz., nausea, vertigo, oppressive sleepiness, muscular pains, and a sense of weakness with tremors and anesthesia. The skin becomes blue, the cyanosis being often very pronounced. The buccal mucous membrane, the gums, the conjunctivæ, the lobes of the ears, the face, the hands, and the feet show the discoloration best. The cyanosis is not due to venous stasis, but depends upon a colored substance in the blood, probably methemoglobin. The men recover if they cease work for a time. The pathology of Raynaud's disease is unknown. No special lesion has yet been noted in either the cardiovascular or nervous systems, central or peripheral. Yet there must be some nervous causes, since the attacks come on after emotional states. The causes of tissue death are: (1) obstructed arterial circulation; (2) impeded venous flow; (3) obstructed capillary circulation owing to diseased walls of vessels; and (4) death of the cells by poisons due to microbes. Excepting in those cases where gangrene has occurred and where the structural alterations in the blood vessels and nerves have been the consequences rather than the cause of gangrene, no constant changes have been found in the peripheral nerves and blood-vessels. It would seem as if some peculiar local change occurred in the tissues of the part affected in Raynaud's disease, whereby either in consequence of the contraction of arteries and veins due to some central nervous condition influencing the vasomotor center, or in consequence of altered chemical states of the blood or pathological changes in the walls of the minute vessels, that either of these conditions singly or combined, but accompanied by poisoning of the cells of the part either through their own toxins or by poisons brought to them, is capable of causing death of the tissues and the formation of a gangrenous slough.

Origin and Differentiation of the Red Blood Cells in Mammals.—At a recent meeting of the London Pathological Society Dr. C. E. Walker presented a paper on this subject, stating that he used the word leucocyte in his paper to cover all the wandering nucleated cells of the body. From a certain class of leucocyte found in the bone marrow of mammals he traced a gradual series of stages of degeneration in the nuclei, and the gradual appearance of hemoglobin in the cytoplasm to cells with a relatively large, round, and almost homogeneous nucleus. During this process the nuclear membrane generally showed some small breaches through which some of the nuclear contents exuded into the cytoplasm. After this Dr. Walker described a large breach as occurring in the nuclear membrane of some of the cells, by which the nucleus was completely disintegrated. In other cells the nucleus apparently disintegrated by exudation through smaller breaches. The centrosomes were retained throughout in a certain proportion of the red corpuscles which had cast rid of their nuclei in this manner. In the bone marrow a very large proportion of the red corpuscles contained remnants of the nucleus. A very small proportion retained these remnants after they had been thrown into the blood stream. Dr. Walker had observed the bodily ejection of the nucleus in these hemoglobin-bearing cells, but only as a post mortem phenomenon. He based his interpretation of the sequence of the changes which he described upon comparison with what happened in degenerating cells in the test of various animals, and upon the changes which he had observed in the nucleated red corpuscles of fœtal ox, reptiles, and birds after removal from the body of the animal. In all these cases the exact sequence of events could be followed with the greatest certainty. He incidentally recorded the presence of two or more centrosomes, often hypertrophied, in practically all the red corpuscles of fœtal and other amphibia.

British Medical Journal, December 29, 1906.

Tenotomy of Inferior Oblique and Consideration of the Conditions that May Call for the Operation.—After describing the technique of the operation, which consists in a division of the tendon of origin through a cutaneous incision, A. Duane discusses the conditions which may call for the operation, namely: (1) Conditions simulating spasms of the inferior oblique. (*a*) Complete stationary paralysis of the superior rectus of one eye. Fixation with the other eye. No true spasm. (2) True secondary spasm of the inferior oblique. (*b*) Partial paralysis or insufficiency of the superior rectus, causing pronounced secondary deviation of the other eye, due to spasm of its inferior oblique. (*c*) Paralysis of a superior oblique or some other muscle, causing secondary spasm of the inferior oblique in the same eye. (3) Primary spasm of the inferior oblique. We must be sure before operating (1) that the condition is permanent and stationary, and (2) that the symptoms are so marked as to call for interference.

Treatment of Unripe Cataract.—W. M. Kulen extols the utility of the McKeown apparatus for intraocular irrigation in cases of unripe cataract. The fluid used is saline solution, 4 gr. to the oz., boiled in a glass flask before use and rapidly cooled to blood heat. The eye tolerates this solution well, and very free intraocular irrigation can be kept up without for a long time where sticky cortex has to be removed without any serious reaction. The absolutely essential conditions are that the solution is sterile, at blood heat, and that the vitreous chamber is not opened. Most a pint should be in the flask for an operation. Irrigation may be done in two stages. The first is injection of fluid under the capsule of the lens immediately after the corneal section and before the usual capsulotomy. The blunt flow needle is much like a fine hypodermic needle, and it should be introduced about half way between the section and the center of the pupil, so as to avoid perforation of the edge of the lens or suspensory ligament. It must also be kept well in front of the nucleus. The use of the needle at this stage is a valuable means of diagnosis of the consistence of the lens. If it penetrates the capsule easily, without moving the lens, the fluid will spread usually and help to opacify the unripe cortex, and irrigation will be useful both now and after delivery of the nucleus. On the other hand, if it does not penetrate the capsule or if it commences to push the lens before it, we have probably to deal with a sclerosed cataract, which will not require irrigation. The section of the capsule is now made, and the body of the lens extracted, after which further irrigation through the nozzle, combined with massage, serves to soften and remove masses of cortex still remaining. In many cases the nozzle irrigation is quite sufficient, the needle not being used.

Eyesight in Relation to Compensation.—T. Fergus refers to the attempts which have been made to derive formulæ by which to assess the damages due for the loss or partial impairment of one eye. He has gathered some data about men possessed of only one eye who were not entitled to compensation owing to their loss of vision from disease, etc. He gives the results obtained in a series of such cases. A great deal depends on what might be called the patient's resource. It seems to the author that it is hopelessly futile to establish a definite relation between a person's wage-earning capacity and his eyesight. Some men with only one eye seem practically helpless, while others get on without difficulty. Another element equally impossible of evaluation is the injured man's truthfulness. The only means which we have of measuring a person's visual acuteness is by letters, or by other objects of known size. But when a patient is placed in front of letters which gradually diminish in size we have no means of testing whether the smallest letters which he reads are the smallest which he sees. He may only read 6/36, while all the time his vision is 6/6. There is obviously a great temptation placed before frail humanity if the worse the vision the greater the compensation. Frequently a witness goes into the box and states on oath that the vision of the injured man is, say, 6/36. What he really should say is that at the examination the patient read letters of 6/36, but as to whether that is his best or not he (the witness) is entirely ignorant—unless, indeed, when he has during the examination found something which would account for such a diminution of the acuteness. Here, therefore, we have another factor which must justify any formula which attempts to express a relation between wage-earning capacity and the form sense. Lastly, and most important of all, there are many kinds of employment in which the form sense does not seem to play any appreciable part. To this category may be added, e.g., all persons who have an expressively high degree of myopia. A young man had worked for several years in a coal pit. He thought he would try to get employment above ground, and accordingly applied to a railway company, but was rejected on account of his sight. He came to the hospital, and it was found that he had a myopia of 15 D in one eye and of 15 D in the other. The acuteness of the better eye was only 1/30 Snellen. Yet this lad had no idea that there was anything wrong with his eyes.

Berliner klinische Wochenschrift, December 24, 1906.

The Spirochete Question.—Schulze considers that by means of his experiments on the inoculation of the rabbit's cornea with syphilitic material he has been able to prove

that syphilis can be transmitted to these animals and also that he has been able to demonstrate the presence in the lesions of the *Cytorrhyctes luis* of Siegel. He is furthermore of the opinion that the structures to be seen in syphilitic material after treatment by the modified Golgi method of Levaditi are only artefacts composed of some tissue element, usually nerve terminals. He points out that these structures are demonstrated most successfully in tissues, such as those of syphilitic fetuses, that have undergone more or less maceration. He has been able to demonstrate them in the cornea of a nonsyphilitic fetus, although only in small numbers, and explains their fewness in this case on the assumption that chemical conditions existing in syphilitic tissues facilitate the staining by the silver method. He gives as a strong argument against those who believe that the silver-stained structures really are spirochetes the fact that in this case the so called spirochetes should also be susceptible of demonstration by the Giemsa method, but states that this is not so. Against the argument, of those who contend that the silver stained structures cannot be artefacts because they are sometimes seen in the lumen of blood-vessels he brings forward the possibility that portions of the macerated wall of the blood vessel, such as the intercellular cement substance, may become detached and take the stain.

Blood Pressure Determination in Man.—Bing gives the theoretical and practical considerations which lead him to conclude that the blood pressure determinations obtained by the ordinary methods in clinical use represent not the end pressure in the brachial artery, but the lateral pressure. Comparative observations made on the two arms, one of which was subjected to either cold or heat, showed that the results obtained by the sphygmomanometer were dependent on the condition of contraction of the vessels below the point of measurement so that changes in the lumen of these vessels produced alterations in pressure without necessarily being attended by any corresponding fluctuations in the aortic pressure.

Münchener medicinische Wochenschrift. December 25, 1906.

Perforation of the Duodenum by a Hairpin.—Mennacher describes a case of fatal peritonitis following perforation of the duodenum caused by a hairpin swallowed about five months previously. The patient was a girl of six years, and for four weeks after the foreign body had been swallowed constipating diet and observation of the stools was kept up. Although the hairpin did not appear, as the child suffered from no inconvenience these precautions were gradually relaxed, and during the following four months the little patient gave no evidence of anything being wrong. She then suddenly developed acute abdominal symptoms, and the possibility of appendicitis or intestinal perforation was considered. In the next few hours no remarkable an improvement in the patient's condition occurred, however, that the operation was postponed. About twelve hours later the peritoneal symptoms had returned with full violence, and on opening the abdomen a diffuse suppurative peritonitis was revealed and it was discovered that the blunt end of the hairpin had pierced the duodenum at the junction of the descending and ascending parts, most of the pin still remaining inside the intestine. Death occurred in the night following. The author calls attention to the length of time that the hairpin must have remained in the stomach, as he concludes that the onset of the acute symptoms must have occurred shortly after its passage into the duodenum, and also to the very striking period of remission of symptoms, which is not an unusual feature in cases of perforation of duodenal ulcers.

The Technique of Staining for Spirochetes. Krauss describes an improvement in the methods for staining spirochetes in syphilitic lesions. The preparations are fixed in osmic acid fumes and stained with Giemsa's solution in the manner indicated by Hoffman-Halle. The chief objection to preparations made in this way consists in the precipitates of dye that always somewhat obscure the field. These may be removed, according to Krauss, by immersing the preparation for about half a minute in a 30 per cent. aqueous solution of tannin, by means of which very sharp differentiation is produced. The spirochetes have a bright red color which is in strong contrast to the colorless or pale pink background. It is stated that the tannin solution never decolorizes the spirochetes.

French and Italian Journals.

Amputation of the Cervix for Hypertrophic Elongation at the Fourth Month of Pregnancy; Labor at Term.—Potocki describes a circular amputation of the cervix which he performed at the fourth month of pregnancy. The elongated cervix protruded the width of a finger below the labia minora and could not be pushed back into the vagina. The cervix in its entire length was hard; the cervical canal was not dilated, the fundus of the uterus was at the umbilicus. After amputation the intracervical mucosa was carefully sutured with catgut to the vaginal membrane. The section amputated measured seven centimeters and showed signs of sclerotic lesions. A natural and rapid labor occurred at term. The child is now six years old. In a previous case of the same kind which Potocki observed the cervix had not been amputated; it did not disappear during labor; the membranes broke and the child died. In this case the fetus had to be extracted by basiotripsy and the patient recovered after suffering many complications. In the operation of amputation the danger of abortion arises, but this danger can be greatly lessened by injections of morphine during the first few days after the operation; besides this the danger of abortion from operations in the genital region during pregnancy appears only in a small proportion of cases.—*Le Bulletin Médical*, October 24, 1906.

Surgical Treatment of Renal Calculi.—During the proceedings of the Association Française d'Urologie, H. Pousson stated that in aseptic renal lithiasis the treatment of choice is nephrotomy. When treating a suppurative calculous kidney the surgeon must take into consideration conditions such as infectious changes destructive of the renal tissue with perinephritis, with or without suppuration, as well as the general condition, before deciding to proceed by nephrotomy or nephrectomy. The present methods of judging the actual condition of the kidneys have greatly reduced the uncertainties of nephrectomy. In using this method fistula and septicemic accidents are avoided and the convalescent period is shortened when the disease is not too deep seated. In discussing the statements of Pousson, Rafin said that the danger of nephrectomy lay in the fact that renal lithiasis often affects both kidneys. The diagnosis could be made by radiography. He showed five calculi which had been diagnosed by radiography, four being extracted by nephrotomy and one by pyelolithotomy. In suppurative lithiasis great care is necessary to prevent infection where catheterization of the ureter of the healthy kidney is employed.—*La Presse Médicale*, October 17, 1906.

Sudden Death from Acute Pulmonary Edema During the Course of Phlegmonous Periamygdalitis.—Louis Albert Ambard describes a patient under his care who, for the symptoms of a mild attack of phlegmonous periamygdalitis had subsided, suddenly died from an acute general edema of both lungs. He considers this case an interesting actual proof of the theories which attribute extremely acute edema of the lungs to trouble of the nervous system. It seems especially to uphold the theory of pulmonary vasodilator inflammation, on account of the irritation of the pneumogastric caused by the compression of this nerve against the cervical region by an inflamed lymphatic ganglion. Careful macroscopic and microscopic examination proved the integrity of the organs usually involved. There was no nephritis, the heart was healthy, the aorta showed no trace of atheroma, nor were there any signs of those valvular lesions, such as mitral stenosis and aortic insufficiency of rheumatic origin, which have, at times, been considered the cause of acute edema of the lungs.—*Comptes des Hebdomadaires des Séances et Mémoires*, August 21, 1906.

Changes in Gastric Chemism Following Gastroenterostomy.—Katzenstein describes the results of experiments on a number of dogs. Gastric fistulas were produced in the dogs and the gastric juice obtained from the fistula was examined both before and after a gastroenterostomy. The results were found to be as follows: After the formation of a gastroenterostomosis large quantities of bile and pancreatic juice enter the stomach; the flow is at first continuous, but varies later with the stage of digestion. The presence of these alkaline intestinal juices diminishes the acidity of the gastric juice both by chemical action and by reducing the secretion. Pepsin does not act in a neutral medium, the pancreatic trypsin acts in a medium which has a temporary acid reaction, but its action is easily weakened. The diastase and the emulsifying ferment act in slightly acid media, but not as strongly as in media which are neutral or alkaline. Secretions of bile and pancreatic juice can be excited reflexly when fats are introduced into the stomach. The author in fact offers a method of diminishing the acidity of the gastric juice after gastroenterostomy.—*La Presse Médicale*, October 20, 1906.

Diffuse Neurofibromatosis.—Christofoletti describes an interesting case of neurofibromatosis in which many nerves, especially among the cranial nerves, were involved. The tumors were in this case all on the left side, whereas they are usually scattered rather symmetrically on both sides of the body. The patient was sixty-seven years old, an age more advanced than usual in such cases. He first

noticed severe neuralgic pains of the left upper arm and discovered a tumor of small size in the same region. Following this he had symptoms which indicated the involvement of many nerves. He had vertigo, myasthenia, uncertain gait, severe occipital headache, somnolence, apathy, and melancholia, while all his mental faculties were intact. All these symptoms indicate a tumor of the cerebellum. The neuralgia extended to the left side of the neck, indicating involvement of the cervical plexus as well as the brachial. The pulse was absent in the whole left arm, from pressure of a tumor on the subclavian artery. The disease involved all three branches of the trigeminus, the lesion being intracranial. There was a total left facial paralysis, from a lesion of the trunk of the nerve in its intracranial portion. The hearing on the left was lost. There was great difficulty in swallowing and paralysis of the velum of the palate from lesions of the hypoglossus, accessorius, vagus, and glossopharyngeus. There was paralysis of the left vocal cord. The chief interest of the case is due to the large number of nerves involved as indicated by the symptoms, while only the one small tumor of the arm could be felt.—*La Riforma Medica*, September 22 and 29, 1906.

Struma the Result of the Diplococcus of Fraenkel.—D. Buttino and F. Cattanea tell us that it is well known that various infections may affect the thyroid gland, especially when the gland is in a pathological condition to begin with. The thyroid may suppurate in typhoid, puerperal fever, pyemia, rheumatism, and malaria. They record a case in which the infective agent was the diplococcus of Fraenkel. This germ becomes a pus producer and localizes itself in other regions besides the lungs. But it is exceedingly rare to find suppuration of the thyroid from this germ, only ten cases being recorded. The patient came into the hospital for a mild pneumonic affection, having a chronic enlargement of the thyroid gland at the beginning of the disease. No pneumococci were found in the blood. There occurred suppuration of both lobes of the thyroid, and in the pus removed the pneumococcus was found.—*Rivista Critica di Clinica Medica*, October 6, 1906.

Differential Diagnosis Between Poisoning with Charcoal Vapors and with Illuminating Gas.—A. Cevidalli and A. Chistoni have endeavored to find a means of diagnosis between poisoning by charcoal vapor and that produced by illuminating gas. This is sometimes of great medicolegal importance in fixing the responsibility for accidental poisoning. The symptoms and post-mortem appearances are very much the same. Poisoning with illuminating gas is more dangerous than that with carbon monoxide, inasmuch as when a gas jet has been left open the flow goes on constantly as long as the pressure in the pipes continues, while in the use of charcoal for heating the flow stops when the fuel is consumed. In poisoning by charcoal there is a deposit of soot about the nostrils and in the respiratory tubes. In cases in which illuminating gas has filtered through the earth the hydrocarbons which give it its odor are removed, and it becomes odorless, and this far more dangerous. The authors experimented on the action of the two gases with methemoglobin as a method of diagnosis. Their results are thus given: illuminating gas transforms a solution of methemoglobin so as to produce a clear, red color, and there is a wide band of absorption in the green of the spectroscope. The blood of man and the ox methemoglobinized behave in the same way with illuminating gas. Co pure, or air, passed through a solution of methemoglobin produces no change in the solution.—*Lo Sperimentale*, Vol. III, Anno LX.

The Cerebellar Syndrome in Malaria.—G. Pecori finds that dysarthria is a rather common symptom in severe cases of malaria, especially of the cerebrospinal variety. It often goes with symptoms of incoordination that are attributable to a localized lesion in the cerebellum. In a case under his care there was complete inability to speak, although cries and moans were continual. It was impossible for the patient to sit or stand erect; there was midriasis, nistagmus, difficulty of muscular movements, and in swallowing. A general muscular relaxation, with normal sensibility and normal reflexes; retention of urine and feces were followed by incontinence. Vision was the last of the symptoms disappeared, but dysarthria remained and defect in the pronunciation of the dentals and lingivals. After six years there was still some dysarthria. The author considers that there was a lesion of the cerebellum due to a polyencephalitis of infective origin. In a case that came to autopsy, in which there was a similar syndrome, punctiform hemorrhages were found in the white substance of the frontal lobes and the gray substance of the cerebellum. —*Il Policlinico*, November, 1906.

Symptomatology of Cancer of the Pylorus.—Leon Vorters reviews this subject in an interesting paper. The stomach is often considered as the organ most frequently invaded by cancer. It can hardly be deemed that the pylorus is the region where gastric cancer is most often found. Statistics show that among 100,000 people there are about fifteen deaths each year from this cause. Pyloric cancer is rare before the age of thirty and after the age of seventy. Following certain dyspeptic disturbances which are rather vague, pyloric cancer may be considered to pass through two stages. The first or initial period is marked by characteristic dyspeptic symptoms, gastric dilatation with retention due to pyloric stenosis. The second or terminal period is that in which the tumor is perceptible and cachexia develops. As has already been indicated, the beginning of this trouble reveals itself by obscure symptoms. Cancer, when it has its seat in the pylorus, almost invariably give rise to pain. In spite of this, however, pain is variable and may be lacking entirely. Vomiting is frequent in all forms of gastric cancer. In cases of pyloric cancer vomiting is almost constant. Hemorrhage in these cases is frequent and varies in the different patients in its appearance, in its quantity, and in its frequency. Pyloric cancer is an affection which has a continuous and progressive course. In the terminal period metastases are looked for. Propagation may take place by the blood-vessels or by the lymphatic route.—*Gazette des Hôpitaux Civils et Militaires*, November 17, 1906.

Three Cases of Gastric Wounds Treated by Laparatomy.—Vavray presents three new observations of gastric injury which were treated surgically. He has now operated on seven patients with gastric injury, with four recoveries and three deaths. He insists upon the necessity of making a large opening in the anterior colic omentum for the exploration of the posterior surface of the stomach in order to see if this part has been injured. An opening which is too narrow renders exploration very difficult, and he has discovered that a large transverse incision can be made without compromising the vitality of the intestinal walls. Even then the opening is often insufficient for proper exploration. In such cases this operator advises exploratory gastrotomy. This increases the danger to the patient. However, its advisability depends upon the indications observed. The writer believes that it is especially useful in injuries by bullets and when the stomach is empty at the time of the accident.—*Revue de Chirurgie*, November 10, 1906.

Tetanus Neonatorum Treated by Baccelli's Method.—Lavinio Miserocchi gives us the history of a case of tetanus neonatorum treated successfully by injections of phenic acid after the method of Bacelli. The child was six years old when it was attacked by trismus, which went on rapidly to opisthotonos and tetanic seizures, with high temperature. Injections of phenic acid were at once begun, with antiseptic treatment of the navel, which secreted some pus. Four or five injections were given daily in sterilized oil. The seizure diminished and the temperature went down. After thirty-four days of treatment the child was cured without having shown any symptoms of carbolic acid poisoning. The type of the disease was severe, with very high temperature, and in general such cases end fatally. This seems to be a good case for a test of the treatment, and its happy ending appears to show that this treatment will be curative when undertaken early. *Rivista Critica di Clinica Pediatrica*, November, 1906.

Decapsulation and Capsulotomy in Nephritis.—Tommaso Costa tells us that we may regard decapsulation of the kidneys as of the greatest value in most varieties of kidney diseases, acute as well as chronic. It is contraindicated in old age, cardiac disease, and albuminuric neuroretinitis, which is the precursor of a fatal ending. The author believes that the benefit is due to a new formation of the capsule which allows the tissue of the kidney, before bound down by the constricted capsule, to expand. New blood-vessels are formed in the new capsule. The epithelial elements are regenerated, but the better nutrition makes them change within themselves so as to better perform their functions. The hyperemia and polyuria which follow the operation aid in the absorption of morbid products within the kidneys, and render the urinary tubules permeable. The author has produced an artificial nephritis in dogs by the injection of a solution of chlorohydrate of hydroxylamine, which produces a nephritis very similar to that seen in the human race. Fifteen dogs were treated in this way; a part were then submitted to decapsulation or capsulotomy, while others were left untreated. Eight of those operated on were cured of the nephritis, while those not operated on died. The author concludes that the decapsulation of one or both kidneys will cure an artificially produced nephritis. Cure is more rapid and progressive in capsulectomy than in capsulotomy. After forty days the capsule is found reformed and thicker and more vascular than before. A unilateral operation, by means of the renal reflex, results in a cure of bilateral nephritis.—*Giornale Internazionale delle Scienze Mediche*, November 15, 1906.

Book Reviews.

Diseases of the Digestive System. Edited by Frank Billings, M.D., Professor of Medicine, University of Chicago, and Professor of Medicine and Dean of Faculty, Rush Medical College. An authorized translation from "Die Deutsche Klinik" under the general Editorial Supervision of Julius L. Salinger, M.D. With Forty-five Illustrations in the Text. New York and London: D. Appleton & Co., 1906.

The best method of giving some idea of the scope of this volume of eight hundred odd pages, which is composed of a series of articles on various diseases of the digestive system by German authors, is to enumerate the subjects discussed, together with the names of the writers to whom they have been allotted. The list is as follows: Stenosis of the Esophagus, by Th. Rosenheim; The History and Clinical Indications of Gastric Lavage, by W. Fleiner; Functional Diseases of the Stomach, by H. Leo; The Diagnostic and Therapeutic Significance of Secretory Disturbances of the Stomach, by H. Strauss; Diagnosis and Treatment of Gastric Dilatation, by F. Riegel; Gastric Ulcer and Gastric Hemorrhage, by C. A. Ewald; Gastric and Intestinal Carcinomata, by J. Boas; Displacement of the Abdominal Viscera and of the Heart, by F. Hirschfeld; Symptomatology of the Diseases of the Pancreas, by L. Oser; Jaundice and Hepatic Insufficiency, by O. Minkowski; Chronic Inflammation of the Liver, by E. Stadelmann; Neoplasms of the Liver and Biliary Passages, by Fr. Kraus; Echinococcus of the Liver, by E. Stadelmann; Gallstones, by E. Neusser; Acute Diffuse Peritonitis, Appendicitis, and Perityphlitis, by O. Vierordt and J. Boas; Examination of the Feces, by J. Strasburger; Diarrhœa, Intestinal Catarrh, and Intestinal Tuberculosis, by W. Fleiner; Constipation and Hemorrhoids, by J. Boas; Mucous Colic and Membranous Intestinal Catarrh, by G. Hoppe-Seyler; Intestinal Constriction and Intestinal Occlusion, by H. Nothnagel. From the foregoing it is evident that the volume is composed of essays by some of the most eminent German-speaking clinicians on a well-selected series of topics concerning the disorders of the alimentary tract, but that the work does not and is not intended to cover the entire subject in a systematic way. As is usual in such compilations, some of the sections are much better than others, but the general average is high and the articles are written in a way to prove interesting and directly useful to the practitioner. The book, therefore, is of a sort to serve as a highly desirable acquisition to any medical man's reference library, but it should not be the first treatise on diseases of the digestive system purchased by the student or young practitioner.

The Ear and Its Diseases. A Textbook for Students and Physicians. By Seth Scott Bishop, B.S., M.D., LL.D., Surgeon to the Post-Graduate Hospital and to the Illinois Hospital, etc. Illustrated with Twenty-seven Colored Lithographs and 200 Additional Illustrations. Four Hundred and Forty Pages. Bound in Extra Cloth. Price, $4.00, net. Philadelphia: F. A. Davis Company, 1906.

Probably no textbook on diseases of the ear, nose, and throat has been used in more American medical schools than that of Dr. Bishop, which has passed through several editions. Objection having been made that the portion devoted to otology was too abridged, the author has prepared a special treatise on this special subject, not only elaborating the ideas expressed in the original work but also introducing much new material. This is especially noticeable in the opening chapters devoted to anatomy of the ear, which, says the author, "has heretofore been a field both dreaded and unconquered by the average student." Many of the illustrations in these chapters are from preparations and sections made by the writer, who has drawn freely on his extensive clinical experience rather than slavishly following the usual beaten tracks so strongly in evidence in many textbooks. Two interesting chapters discuss the ill-effects of various diseases and drugs on the ear, and reference is also made to the relation of ear diseases to life insurance risks.

The Health-Care of the Baby. A Handbook for Mothers and Nurses. By Louis Fischer, M.D., Author of "Infant Feeding in Health and Disease," "A Textbook on Diseases of Infancy and Childhood"; Attending Physician to the Willard Parker and Riverside Hospitals; Former Instructor in Diseases of Children at the New York Post-Graduate Medical School and Hospital, etc., etc. New York and London: Funk & Wagnalls Company, 1906.

In this condensed manual the writer gives many details in relation to ventilation, clothing, and bathing which should be familiar to every mother and nurse. The most important part of the book consists in the suggestions and advice pertaining to infant feeding in health and in conditions of stomach and bowel disorder. The management of rashes and fever is considered. Many hints are given as a guide to the mother during attacks in her children of measles, skin diseases, croup, and like affections. First aid suggestions in cases of accidents and poisoning, and bad habits are discussed. The last chapter treats of external applications and the medicine chest. The young mother and nurse will find this little volume very helpful.

Conferences on the Moral Philosophy of Medicine, prepared by an American Physician. New York: Rebman & Co., 1906.

This modest volume treats of many subjects essential to the well-being and success of every medical man, be he student or physician. The following excerpt from the introduction is a peculiarly illuminating syllabus of the subjects treated of. The author says "that the systematic teaching of medical morals should constitute the early part of the student's education is evinced by the frequently expressed desire of young men to obtain the right kind of information for guidance in their professional relations and obligations. The moral philosophy of medicine, comprising as it does the science of the physician's duty in all his acts and concerns, the thorough knowledge of the law of medicine, and of the relations of the student as well as the graduate with his associates and other members of the community seems a suitable title for these colloquies which consist of an exposition of some of the general and special principles of conduct of the aspirant to medical studentship, of the matriculated student, of the hospital interne, and of the young practising physician, and include considerations on physicians of the past and present, on medical teachers, schools, and students, on the early cultivation of the senses as essential to the proper conduct of the study and practice of medicine, on the evolution of medical morals, on the special relations of the physician and patient, of the physician and colleagues, and of the profession and public, besides a discourse on the language of medicine; another on young writers and speakers, and a third on the length of life of physicians."

We commend to young men the chapters on the "Aspirant to Medical Studentship," on "Physicians of the Past," and on "Teachers, Schools, and Students of Medicine," since they contain much necessary information which will aid a man so materially in his conduct and conceptions of medical life, and tend to equip him for successful effort. In like manner the directions to the "Matriculated Student," to the "Graduate as Hospital Interne" are most impressive. One of the best chapters in the book is upon "The Young Practising Physician." The chapter on "The Evolution of Medical Morals," which treats of the earliest principles of conduct and shows how the obligations of physicians have gradually been formulated and crystallized into practical demonstration is most valuable and commands close attention. The question of the relation of the physician and his patient is handled in a masterly manner, and the duties of each one to the other are brought out with the greatest clearness and simplicity. These chapters, together with that on the "Physician, Profession, and Public," embody an epitome of character, conduct, and endeavor which should be generally studied. The whole book is a *vade mecum*, which should be in the hands of all medical men. In reviewing a work such as this, with its lofty sentiments and aspirations and its pure, practical, Christian teachings, one would fain wish that its author had not clothed himself with anonymity.

Photoscopy (Skiascopy or Retinoscopy). By Mark D. Stevenson, M.D., Ophthalmic Surgeon to the Akron City Hospital; Oculist to the Children's Home, Akron, Ohio. Philadelphia and London: W. B. Saunders Company, 1906.

This new competitor for favor with those who determine the refraction of the eye is written by one who has studied the subject profoundly and who is familiar with the wants of those pursuing this branch of medical practice. The term "photoscopy," which is employed as the title of the work, is somewhat unfortunate, since it is not sufficiently specific to indicate the method to which it is applied. The volume, which includes 126 pages, is well written, well printed, and well illustrated. The text is divided into five chapters. Chapter I. contains suggestions for beginners and describes the instruments necessary for the work. Chapter II. deals with the underlying principles of the method, considers the intensity and kind of light desirable, and describes the various phenomena observed. Chapter III. takes up the practical application of the method. Chapter IV. is devoted to general considerations, cycloplegics, aids to accuracy, etc. Chapter V. is historical. A bibliography and index follow. The work ranks well with others of its kind.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Held at Baltimore, Md., December 11, 12, and 13, 1906.

THE PRESIDENT, DR. GEORGE H. NOBLE OF ATLANTA, GA., IN THE CHAIR.

Sulphate of Sparteine in Surgical Practice.—Dr. STUART MCGUIRE of Richmond, Va., said he believed he had accidentally discovered in this drug a valuable remedy for the prevention and treatment of postoperative suppression of urine. In the last five years he had lost more cases from postoperative suppression of urine than from all other causes combined, and this, despite the almost routine use of chloroform as an anesthetic. The cases had usually been those with preexisting nephritis from sepsis or cholemia. Shock had not apparently been a factor, as the condition would not develop for twenty-four or thirty six hours. A patient operated on for retention of urine or for jaundice due to obstruction of the common duct would do well for one or two days, and just as the patient was thought to be out of danger there would come the news that he was passing no urine. He would become restless, then listless, would develop a stupor which would rapidly deepen into coma, and would die with all the symptoms characteristic of uremia. In the treatment of this condition he had tried water by mouth, under the skin, and in the rectum; hot packs and vapor baths; cups and counter-irritants; strychnine, digitalis, and nitroglycerin; calomel and saline purgatives, and in one case stripping the kidney capsules, with uniformly bad results. Two years ago he began empirically the use of sulphate of sparteine, and he now had a record of six cases in which he was sure the drug was the means of saving the patient's life. Its therapeutic effect was to increase the blood pressure, make the pulse slower and stronger, and act as a powerful diuretic. Its action was manifest in thirty minutes after administration and lasted for four or six hours. To get results sulphate of sparteine must be given hypodermically in from one to two grains, repeated every three to six hours. Its use should not be delayed until suppression of urine existed, but it should be prescribed as prophylactic as well as a curative agent. He did not claim it was a specific, but it should be employed to the exclusion of other measures such as purgatives, transfusions, and hot packs. He did believe, however, from actual experience, that it was preferable to the drugs of the digitalis type in rapidity of action, ease of administration, and efficiency of results.

Dr. WILLIAM PERRIN NICOLSON of Atlanta, Ga., had used sulphate of sparteine in a similar way. He preferred it as a heart tonic to digitalis. Therapeutically, it combined the virtues of being a powerful heart tonic and of dilating the capillaries. An important point was to give it in large doses—say two grains. Usually it was put up by drug manufacturers in doses of one tenth of a grain. Its value depended on large doses. He recalled one case in which suppression of urine lasted for forty-seven hours, but the patient finally recovered.

The Comparative Advantages and Disadvantages of Hysterectomy and Removal of the Body of the Uterus.—Dr. J. WESLEY BOVEE of Washington, D. C., said it was found that an important proportion of cases of tumors thought to be simple fibromata or myomata had in reality taken on malignant degeneration or were complicated by a malignant degeneration of the corporeal endometrium. Carcinoma of the cervix had been detected within a few days after the removal of the body of the uterus, showing clearly it existed at the time of the supravaginal amputation. In innumerable instances removal of the cervical stump had been done at the same sitting, prompted by discovery of malignancy in the uterine body just removed. Not a few observers had seen cases in which fibromata had existed for years, the patients declining operation, and cancer of the cervix developing subsequently, with a fatal result. He had seen two such cases. One of them he saw first in consultation in 1880, and again a few months before her death in 1902. That cancer of the cervix occurred more frequently with uterine fibroids than without them had not been proven. The same could not be said of cancer of the body of the uterus. Admitting that the presence of fibroids in the uterine body had no influence with the development of cancer of the cervix, valuable information from statistical tables on the complications of fibroids is available to demonstrate the remarkable increase in the frequency of cancer of the body of the uterus as compared to its existence in the cervix as such complications. The percentage of cases of cancer located in the body and the cervix was generally estimated by many competent observers as 10 per cent. and 90 per cent. It was likewise conceded that the ratio was markedly changed in the presence of uterine fibroids. C. P. Noble found, in a study of 2,274 cases of uterine fibromata, that cancer in the body was found in 45, and of the cervix in 10 of them. This changed the percentages to 74 in the body and 26 in the cervix. The proportion of cases of cancer of the body of the uterus to those of cancer of the cervix was thus shown to be increased twenty six times in the presence of fibroids. Williams had found but four cases of cancer of the body of the uterus to 156 involving the cervix in 160 consecutive cases of uterine cancer coming under his observation. Winter, in studying 2,331 cases occurring in Germany, found the proportion was one to fifteen. Noble suggested the proportion of cases of cancer of the uterus to those of cervical cancer was about one to ten. Sutton had in 500 cases of fibroids of the uterus 63 that were more than fifty years of age. In eight of the 63 cancer of the body of the uterus was microscopically proven, and in two primary cancer of the Fallopian tube was noted. He had had 23 cases of cancer of the body of the uterus, in eight of which fibroids were present as a complication. Piquand had collected 179 cases of cancer of the body of the uterus complicated by fibroids, and had had in 1,000 cases of fibroids cancer of the body of the uterus as a complication in 15 cases. Robb had found that of 42 cases of cancer of the uterus six of them were of the corporeal variety, a proportion of one to six. Complete extirpation of the uterus was not an operation, even by the abdominal route, that necessarily taxed the patient's vitality to an extent appreciatively greater than did the removal of the body alone. The vaginal route was a much easier and more commonly practised operation than the removal of the body and not the cervix. Objections to the removal of the cervix with the body because of weakening of the vaginal roof and shortening the vagina were practically nullified by suturing the round and broad ligaments to the vaginal walls, and the fact that in employing the vaginal route these objections were forgotten. As against the removal of the cervix, when the body of the uterus was removed, the abdominal route was the only one to be considered. The comparative ease of the amputation was of moment only in critical cases. The cosmetic effect to young women deserved more consideration. Oftentimes retention of the portio vaginalis was deemed by them to be of great value. It would seem that in the young woman without a family history of malignant disease and in the absence of uterine growths the cervix should not be removed if the body was to be taken out by the abdominal route. In very critical cases in which the body of the uterus was to be removed by that route, even in the presence of tumors, it would occasionally be advisable not to remove the cervix. In practically all other cases the cervix should not be saved, and this injunction would seem to be the stronger in old women, particularly if evidence of uterine growths be present.

Dr. Isaac S. Stone of Washington, D. C., had never regretted having left the cervix. So far as malignant disease was concerned, it had been his good fortune to save two patients by subsequent operations, who had what was called subtotal hysterectomy done, with stump remaining, which was subsequently found to be malignant and operation was done. Both of these patients were still alive. However, one was a case of sarcoma. He thought a large number of surgeons were well satisfied with the mortality of the Baer operation of leaving the stump.

Dr. Henry T. Byford of Chicago said that no cut-and-dried rule could be laid down to take out the cervix in the class of cases under discussion. One would not think of removing the cervix in a young woman unless there was demonstrable malignant disease. Even in an old woman it was a dangerous procedure, and one attended with great difficulty. The cervix should not be removed unless there were good reasons for so doing.

Dr. Maurice H. Richardson of Boston recalled but one instance in which cancer of the cervix developed after supravaginal amputation for fibroids. While he had not looked up his records, he should say that cancer of the cervix was very rare after such operations.

Dr. Herman J. Boldt of New York said that so far as the occurrence of malignant disease in the cervix after supravaginal hysterectomy was concerned, it must be admitted that it did occur. He did not believe, however, that if the cervix was left it was a causal factor in the production of malignant disease. So far as the relative risk between supravaginal amputation and panhysterectomy was concerned, he did not consider that it cut any figure. One who was accustomed to doing pelvic surgery could do one operation as quickly as the other. The main question was, What was the condition of the vaginal vault subsequently? In the majority of instances it made no difference whether there was a good vaginal vault following supravaginal amputation, or whether there was a vaginal vault with more or less cicatricial tissue in it, but it did occasionally make a difference, for he had seen patients become markedly neurasthenic as the result of scar tissue in the vaginal vault, and he did not consider it desirable to do a panhysterectomy when the cervix was in a fairly normal position. When the vaginal portion of the cervix was diseased, the vagina torn, and the cervix eroded, the cervix ought to be removed; but otherwise he thought it was just as well to leave it because it made a better pelvic floor.

Dr. Robert S. Hill of Montgomery, Ala., said there were as potent reasons for leaving the cervix in some cases as there were in others for removing it. If we considered the anatomy of the pelvic floor we must conclude that the removal of the cervix weakened the pelvic diaphragm, and therefore postoperative vaginal hernia was more likely to occur. The verdict of the majority of the profession was that panhysterectomy was an operation of greater magnitude than supravaginal amputation of the uterus, when we considered the increased traumatism to the parts, the increased liability to injury of the rectum and bladder, and the increased chance of interfering with the ureters through cicatricial tissue, as well as the increased chance of infection by entering the vagina. He could not agree with the statement that panhysterectomy as an operation was of no greater magnitude than was supravaginal amputation of the uterus. This might be true in the hands of the most expert hysterectomists. But we must consider what could be done by the average surgeon, and not by the men of superior skill in the performance of hysterectomy. When the subject was considered from this standpoint, then it would seem to the speaker that supravaginal amputation of the uterus still had a place in the category of legitimate surgical procedures. As to the amputation of the body of the uterus increasing the chances of cancer of the cervix, he was not aware of any evidence which supported that position.

Extrauterine Pregnancy.—Dr. O. L. Shivers of Marion, Ala., reported two cases of extrauterine pregnancy.

An Improved and Accurate Method of Locating Foreign Bodies with the X-Ray.—Dr. Robert Carothers of Cincinnati, O., said the most important step in foreign body surgery was some definite idea of the location of the foreign body. The *x*-ray had been of untold value in developing this step. Stereoscopy as applied to radiography, called stereoskiagraphy, was the most improved method, and would seem to give the most accurate location of a foreign body. This idea had been worked up by many radiographers in different parts of the country independently of each other. The ordinary *x* ray plate looked flat. The stereoscope gave a perspective view very much as if the parts (bone and bullet) were before one in nature. Two separate plates were made of the same part without changing in the least the position of the part skiagraphed, which was placed on the compression diaphragm table, the compression diaphragm itself being discarded, on a hollow board or plate-holder, with a metallic bottom, so that the rays might be partially obstructed, and in this way one plate could be removed and a second supplied. The tube was held in the tube-holder, and with the use of a plumb-bob it was carefully centered through the center of the part to be skiagraphed onto the center of the plate. The plates were made with the tube placed one and three-eighths inches to either side of this central point, so that they were made from points two and three-quarter inches separated from each other, corresponding to the distance between the human eyes. The developed plates were placed in highly illumined boxes facing each other, and were from them reflected into two small looking-glasses which were placed at a right angle to each other with the apex of the angle placed between the eyes of the observer in the stereoscope. One now looked into the two looking-glasses, each eye in a separate glass, saw a separate plate; then by adjusting the plates and the stereoscope to get an exact focus, the two plates were made to look as one, and it would appear that there was one looking-glass behind which the observer looked, reflecting the object back onto the retina, producing a perspective view. This method was of especial value in locating foreign bodies in the spine, thorax, or abdomen, where it was almost impossible to get a plate which was not flat by any other method.

The Surgical Treatment of Thyroid Disease Based on Three Hundred Personal Observations.—Dr. Chas. H. Mayo of Rochester, Minn., said the medical profession of America was taking a progressive position in recommending operation as a cure for goiter, including also exophthalmic goiter. The simple goiters in girls at puberty were not included in this class. Excepting operations for malignancy and Graves' disease, the great majority of operations were those of expediency and not of necessity. Therefore, a low operative risk was imperative. In uncomplicated cases the mortality following operations was almost an accidental one. There were 110 cases of Graves' disease, with nine deaths, and but two of these were in the last sixty-four operations. In two sarcomas and six carcinomas there was one operative death, which occurred on the third day. Aside from those recorded, there was one death from pneumonia on the eighth day. Pathologically, there was a change in the gland which was essential to Graves' disease or hyperthyroidism. This was in the greater number, size, and shape of the cells, and in the lack of normal colloid. Patients were prepared as to lung complications, and the rhythm and tension of the pulse, which should be carefully investigated, as they were the danger signals. Very rarely was local anesthesia employed, the preference being for the open drop method of giving ether. The patients received from 1/120 to 1/150 grain of atropine and one-sixth of a grain of morphine, twenty to thirty minutes before the administration of the anesthetic. The position of the patient was head up (reverse Trendelenburg), with a roll of gauze under the

neck to cl[illegible] small tumor. A transverse curvilinear incision was made through the skin and platysma muscle, the sternohyoid muscles being separated at the midline. In exophthalmic goiter and complicated cases the anterior muscles on one side at least were severed as high as possible over the thyroid to preserve the nerve supply and break the scar effect. Cysts and encapsulated growths were enucleated. Other goiters were extirpated, care being exercised in preserving the parathyroids to prevent tetany and in protecting the recurrent laryngeal nerve. In this one was aided by leaving the posterior capsule of the gland in the extirpation. Sufficient gland substance should be preserved to prevent myxedema, and, as it depended upon the character of the gland, no definite rule could be given as to what constituted the proper amount.

Dr. George W. Crile of Cleveland, O., said that in a series of 114 operations upon the thyroid gland, his smaller experience had compared very well with the conclusions reached by Dr. Mayo, with the exception that he had been unable thus far to get as low a mortality as was reported by Dr. Mayo from operations in the presence of hyperthyroidism. In the late cases of colloid goiter of long-standing, if symptoms of Graves' disease appeared, he had found that operations on this class were comparatively simple and safe. Young persons with acute Graves' disease, coming on without previous goiter apparently, appearing with other symptoms, he had found to be great risks from an operative standpoint. Of the 114 operations upon the gland, there were five cases of carcinoma and five of sarcoma. In one of the cases of carcinoma the author noticed unmistakable symptoms of Graves's disease. He had not had a fatality in any case of Graves' disease engrafted upon a chronic goiter, but he had had three deaths in twenty cases of acute Graves' disease following operations.

Dr. Randolph Winslow of Baltimore said he had had the opportunity of seeing some surgical work on the thyroid gland done abroad this summer at the Kocher clinic and elsewhere, and had been particularly interested in the anesthetic employed in these cases. Personally, he had been using scopolamine-morphine anesthesia by injection as a means of general anesthesia, and the infiltration of the skin with the Schleich solution for strictly local anesthesia, and found that it worked well, and that, as a rule, the patients did not complain.

Toxemia of Pregnancy.—Dr. W. M. Jordan of Birmingham, Ala., called attention to the nonspecific nature of the liver lesions in cases of toxemia of pregnancy, and said that much the same character of changes occurred in toxemias from other causes. There was a decided tendency for toxemia cases to get worse after the uterus was emptied, except in the case of eclampsia, which for special reasons was not considered in the paper. The cause of this behavior of toxemia cases was attributed to a probable increase in the preexisting toxemia through the addition of toxins resulting from the process of involution of the uterus. For this reason pregnancy should be terminated at an earlier date than would otherwise seem necessary, as this probable post-partum increase in the toxemia must be allowed for. Attention was called to the probable unfavorable influence of anesthesia, as most of the inhalation anesthetics were to some extent liver poisons. Speaking of the treatment, the writer expressed himself as being a firm believer in radicalism. He advised that labor may be terminated as soon as it became evident that the symptoms were of toxemic origin. The reasons given by him were the impracticability of influencing the antitoxic function of the liver, and the unreliability of treatment directed against the toxemia itself.

Dr. D. F. Talley of Birmingham, Ala., read a paper in which he reported eight cases of toxemia of pregnancy.

Cholecystectomy, when Indicated; Some Operative Sequelæ.—Dr. I. S. Stone of Washington, D. C., said that cholecystectomy had become popular because cholecystotomy, or rather cholecystotomy, had frequently failed to cure patients with gallstone disease. He preferred the designation as just stated because the mere finding and removal of gallstones frequently failed to cure many of the invalids who had pain, jaundice, or other symptoms of some mischief about or within the biliary passages. Some operators spoke of dilatation of the common and hepatic ducts as a result of cholecystectomy, and Robson was convinced that this dilatation was a compensatory and perhaps a conservatory action, although he had found that stones developed in such dilated duct as they did in the gall-bladder. Cholecystectomy sometimes failed to prevent a recurrence of colics and of other symptoms which necessitated operation. An important question, therefore, naturally arose, Under what circumstances should the gall-bladder be removed? This question could not be answered until the possibility of definite knowledge of the hepatic and common ducts was considered, especially their patency and contents, and if they were the seat of an infection. A careful review of the recent literature convinced the author that however popular this operation had become, the bad results had not as yet been reported as generally as would appear desirable. Nearly all of those who favored cholecystectomy as an operation of choice agreed to operate when the gall-bladder had, by reason of trauma, infection, or malignant disease, become either useless or dangerous. They say, however, that the operation should add very little to the risk involved in a cholecystotomy. The Mayos removed two out of every five gall-bladders they inspected. They performed a cholecystectomy under the following conditions: When stones were lodged in the cystic duct, the removal of which would leave permanent interference with drainage; when the disease was confined to the gall-bladder, and when it was filled with pus or any fluid or bile which had undergone septic change; when the gall-bladder had become greatly thickened or had lost its function, or was the seat of inflammation without stone in which the liver ducts were not involved, or in malignant disease. The mortality of cholecystectomy had been compared to that of cholecystotomy. The writer thought, however, that very few would succeed in obtaining the low rate reported by the Mayos, who had a record of 1.37 per cent. for cholecystotomy and 1.64 per cent. in cholecystectomy. The author thought the two operations could not be compared for safety in the hands of most operators. Cholecystectomy would be performed by all surgeons for conditions which were a result of severe, long-standing disease which had caused any complications, besides the changes in the gall-bladder itself. On the other hand, cholecystotomy was one of the least dangerous operations in abdominal surgery when the patient had only gall-bladder disease, or possibly a stone with healthy bile. Therefore, the author thought that Robson's figures, 57 operations, 33 of which were for gallstones complicated by various morbid states, with a recovery in 32, and 13 of which were for fistula, were without signification, unless compared with precisely similar cases in the hands of others. The same might be said of 72 cholecystectomies collected by Klieber, with a mortality of 16, 7 of which were due to the operation. The contraindications to cholecystectomy were not numerous, but were of great importance. All the authors agreed upon one point, namely, the propriety of leaving the gall-bladder for drainage purposes in pancreatitis, especially the chronic interstitial variety. The same opinion was expressed by most authors regarding the propriety of leaving a gall-bladder when a cholecystenterostomy might be needed, as in certain common duct obstructions. The writer's experience with cholecystectomy had been satisfactory in some particulars and he found it especially useful in those cases where the gall-bladder had been out of use for a long time. In contracted bladder with an open choledochus, in obstructions of the cystic duct, whether due to stone or other cause, which have resulted in permanent alterations of either bladder or duct, he found the very best indications which would assure perfect cure. In cholelith-

iasis he had had two unfortunate results, because stones continued to pass at intervals after the removal of the gall-bladder. He knew of a third case in the practice of another surgeon where the same difficulty occurred. Cholecystectomy necessitated a better and clearer knowledge of the hepatic ducts than we had hitherto possessed, or the operation would fall into ill favor. The demand at the present time was for a safe and practical method of insuring patients against subsequent attacks of pain, jaundice, or any kind of distress after gallstone operations.

Dr. Robert T. Morris of New York said that in the past surgeons groped over the abdominal wall in the dark, and it was only recently that they had touched the button and turned on the light. He thought that surgeons could turn on the light on this subject if they included all gallstone and cholecystitis cases under one heading, and called them cholecystitis cases and adhesion cases. Adhesions in the region of the gall-bladder and bile ducts would produce the same symptoms as gallstones, whether gallstones were present or not. He cited a case in point on which he had operated. Proper selection of cases was everything in surgery. With increased experience and further observation, he inclined more and more toward the complete removal of the gall-bladder, for the reason that there was a chronic infection going on all the while in many patients.

Dr. W. P. Carr of Washington, D. C., thought surgeons should consider these cases more as instances of cholecystitis and the gallstones as incidental, when it was remembered that gallstones did not cause any symptoms until they produced cholecystitis or obstruction of the common bile duct. It was really a cholecystitis or an obstruction of the bile ducts that led to the diagnosis of gallstones. The gall-bladder should be left unless there were positive indications for its removal.

Dr. Samuel Lloyd of New York said the possibility of an occlusion of the duodenal opening in gallstone cases was not infrequent. He had operated once for congenital closure of the opening from the ampulla of Vater into the duodenum. In a number of gallstone cases surgeons found a very much distended common duct, that is, the duct was distinctly larger than usual, and one should suspect occlusion at the ampulla of Vater, the stone coming down and acting as a ball-valve, pushing against the duodenal opening, producing an inflammatory condition, and finally contraction. The only hope of possible recovery of patients with this type of trouble was to do a choledochoduodenostomy. He spoke of inspissation of the bile throughout the ducts in some cases.

Dr. Henry O. Marcy of Boston referred to the early history of surgery of the gall-bladder and gall-ducts, and said he had written a good deal on this subject. If anyone would take the time to look up the early literature he would find that Marion Sims in his time went over the ground as thoughtfully and carefully as anyone could do it to-day. Eighteen years ago Dr. Marcy operated on a woman for the removal of a gallstone in the common duct. A few weeks ago he operated on the same patient for the purpose of releasing adhesions which had caused biliary obstruction. The woman recovered from the operation.

Dr. J. Montgomery Baldy of Philadelphia said that in many cases a diagnosis of gallstones or of gall-bladder disease was made, yet at the operation no gallstones or disease was found. No adhesions, no cancer, and no occlusion were found; yet the patient had undoubted symptoms, so far as one could tell, of long-standing gallstone trouble. On the other hand, in other cases operations had disclosed disease of a gross character of the gall-bladder; the patient had been relieved apparently, but after leaving the hospital there was a return of the symptoms, even after a secondary operation or cholecystectomy. He recalled one case of long-standing of that character. He admitted that this entire field was as yet very largely unsolved, and so far as his own practice was concerned, there were still elements of doubt both diagnostically and pathologically.

Dr. Joseph Price of Philadelphia reported four recent cases, and said that in two, when he opened the abdomen, he had to side-step to get out of the way of the gallstones. The patients were dying, and he was called to see and operate on them because they were dying. They were not suitable for the removal of the gall-bladder. He thought if he had attempted to remove the gall-bladder in these cases he would have lost the patients on the table. He made toilets, drained, put in coffer-dams, and the patients were now well.

Dr. Frank Martin of Baltimore called attention to two cases of cholecystectomy which he reported in 1895. Since that time he had not changed his opinion, although he had not operated on many cases since. He had resorted to cholecystectomy in fourteen cases out of sixty. In most of the fourteen cases there was a chronic cholecystitis, with disorganized gall-bladder, and acute gangrenous infection. In two or three of them there was an acute gangrenous inflammation of the gall bladder. In these cholecystectomy was followed by excellent results. He had had no deaths or serious shock following the operation.

Dr. Howard A. Kelly of Baltimore said that when he operated for any intraabdominal pathological condition it was now his practice to examine the gall-bladder, among other organs, to determine whether it was diseased or whether gallstones were present or not. He believed in cholecystectomy where the gall-bladder was grossly diseased, although one could not always do an ideal operation. He recalled two cases in which an ideal operation could not be done on account of the great density of the adhesions.

Dr. Charles H. Mayo of Rochester, Minn., said that in their clinic they occasionally operated, after having made a thorough examination, and thinking they had a case of gallstones to deal with, and found no stones. It was rare, however, for them to diagnose gallstones or disease of the bile ducts, even though no stones were found, without finding some abdominal condition which would have made it necessary to operate. He did not think a patient cared whether he had gallstones, duodenal ulcer, or ulcer of the pylorus, if he could be relieved. In other words, the patient had no special preference, although he might think it nice to have the gallstones in a bottle to show to his relatives and friends, proving that he had had that trouble. Some years ago they operated and found a blue gall-bladder, which was ordinarily considered a healthy gall-bladder, but covered with adhesions. They drained such gall-bladders and tried to relieve the adhesions. Two of these cases, however, were recperated, one a year afterward, the other two years thereafter, for the same condition, and at that time they found that a duodenal ulcer was the cause, which had been overlooked at the first operation.

The Treatment of Hemorrhage by Direct Transfusion of Similar Blood.—Dr. George W. Crile of Cleveland, O., said the basis for the clinical use of transfusion of blood in the treatment of hemorrhage was as follows: That normal blood of an individual of one species was physiologically equivalent to that of any other individual of the same species, and was therefore interchangeable; that the vascular systems of two individuals might by an end-to-end anastomosis of vessels be united, that such union might be accomplished so as to approximate intima to intima; that the blood that was transformed across this artificial continuity did not come in contact with any foreign body or any tissue but the intima; that under these conditions blood would not clot and the rate of flow and the amount transferred were under immediate control. Only the gravest and apparently hopeless cases had thus far been transfused. Altogether fourteen clinical cases had been observed. All were done painlessly under morphine and cocaine anesthesia. No unfavorable symptoms of importance had been noted. The donors had regained their lost blood in from five to six days. Every donee had felt immediate improvement. Striking evidence of this had

been shown in the facies, the improved circulation, and the feeling of well-being and even buoyancy. The technique was by no means simple, and must be carried out with absolute precision to prevent clotting. In no instance was there observed nephritis, hemoglobinuria, agglutination, hemolysis, or laking of blood. The transfused blood apparently exercised no unfavorable influence on its new host, and the latter none upon the new blood. The blood of individuals of the same species, therefore, seemed to be physiologically interchangeable. Certain cases of pathological hemorrhage had been cured by the addition of fresh normal coagulable blood. Transfusion in a case of pernicious anemia was tried with totally negative results. Partly on the basis of Wright's work on opsonins and partly on other grounds, two cases of transfusion after bleeding in tuberculosis had been done. In every instance in the research and in the clinic the effect of hemorrhage had been overcome by the replacement of the lost blood by means of transfusion. He was not yet ready, however, to reach conclusions or to make deductions or predictions. This was but a report of progress.

The Management of Laparotomy Patients and Their Modified After-Treatment.—Dr. HERMAN J. BOLDT of New York, in a paper on this subject, said that no particular preparatory treatment was necessary for patients upon whom it was intended to do an abdominal operation, unless the operation involved the opening of the stomach or the bowels. Stomach lavage was of benefit at the conclusion of the operation. Patients should not be kept unnecessarily under an anesthetic. The application of a tight bandage around the upper part of the thighs to keep a blood reservoir in the lower extremities in exsanguinated and very weak patients, was excellent. The same might in exceptional cases be done with one of the upper extremities. These bandages were taken off as soon as the operation had been completed, and thus more blood was thrown into the trunk. The administration of strychnine during and after an operation should be used with more care than was usually done. The intravenous infusion of a 0.9 per cent. saline solution should not be too long delayed when the condition of the patient made it evident that its employment might be of benefit. In instances of large myomata, where the patient had been much exsanguinated by hemorrhage, it was desirable that the infusion be begun as soon as the patient was fully under an anesthetic, so that by the time the operation had been completed about one thousand to fifteen hundred c.c. might have been infused. The application of a very simple dressing over the wound, and the adjustment of a snugly-fitting Scultetus bandage made of oxide of zinc plaster were made. The administration of a dose of morphine was desirable if there was restlessness or pain, the medication acting clinically as a heart stimulant. The author allowed regular diet and unrestricted mobility within twenty-four hours after the operation, unless specially contraindicated. Patients were allowed to get out of bed as soon as possible after an operation. The author avoided forced catharsis before the first four or five days after an operation, unless there was a special indication for it. In cases where resort to vaginal drainage was had, or where it was evident that there would be some secretions intraperitoneally after an operation—as in purulent cases and oozing from torn adhesions—trunk elevation was employed as soon as the patient was put into bed. For this the employment of a bed lifter, which the author exhibited and described, or the placing of high blocks or chairs under the head of the bed, was preferable to back-rests.

The Treatment of Senile Gangrene.—Dr. EDWARD H. OCHSNER of Chicago called attention to the fact that there were two distinct types of senile gangrene, the first occurring in cases with only moderately generalized arteriosclerosis, but in which there was a distinct mural thrombus. In this class of cases there was an early formation of a distinct line of demarcation, and it was best to delay operation until this line of demarcation had become well established, and then to amputate directly through the line of demarcation. In the second class of cases there was a marked generalized arteriosclerosis, the whole affected extremity was markedly involved, there was no tendency to the formation of a line of demarcation, and an early high amputation was indicated.

(To be concluded.)

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held September 18, 1906.

DR. W. F. CAMPBELL IN THE CHAIR.

The Water Supply of New York.—Mr. CHAS. N. CHADWICK, Commissioner of Water Supply of New York, read this paper. He referred to the fact that five years before the same subject. His object now, as then, was to describe the work that was being done to increase the water supply of New York. Ten years ago the Merchants' Association and other civic bodies began the agitation, which resulted in the appointment of a committee composed of delegates from the Chamber of Commerce, the Manufacturers' Association, and the Board of Fire Underwriters. In 1900 a board of eminent engineers was appointed. This selected the Catskill region as the place best adapted to furnish the increased water supply. The Adirondacks had been considered. The Housatonic watershed and the Ten Mile Creek had been rejected on account of interstate complications. The Hudson River as a source of water supply was rejected on account of its pollution and the necessity of building a filter for its water. If the Adirondacks region had been accepted it would have been necessary to build a reservoir at great expense in this remote locality. The Catskill watershed appeared to be the one best fitted to furnish the water most economically. It was, of course, necessary to divert the water from the Esopus, Rondout, and Schoharie. For the prosecution of the work the New York Board of Estimate appropriated $161,000,000. A State commission had to be appointed to adjust the claims of towns whose supply of water might be diminished by the utilization of the Catskill watershed. The enormity of the task that confronted the engineers was illustrated by the fact that 230 miles of territory had to be surveyed in order to find the best eighty miles for the aqueduct. In addition to the complex organization of the various corps of engineers, there was established a laboratory in which analytical chemists determined the nature of the various soils, the tensile strength of cements, the strength of concrete, etc. The peculiar geology of the Hudson River presented a difficult problem for solution. It was decided to tunnel under the Hudson River at Stony Point. One of the most difficult problems was that of running an aqueduct under the Rondout Valley. The plans included the building of a reservoir in the Catskills, having a length of fifteen miles and a width of one and a third miles. The enormity of this undertaking was to be appreciated by considering the fact that in building the reservoir eleven villages were to be wiped out, and a portion of the Ulster and Delaware Railway had to be removed. An additional reservoir was to be built at Kensico, having a fifty days' supply, and at Scarsdale, a filtration plant. It was estimated that at the cost of $161,000,000 the completed improvements would yield a supply of 500,000,000 gallons of water per day. The plans included an aqueduct to Long Island which would yield 52,000,000 gallons per day. For speedy relief it was intended to construct first the aqueduct from Stony Point to Eshoken reservoir, a distance of fifty-eight miles, to empty into the Croton watershed. This was to be accomplished in eight years.

The Underground Water Resources of Long Island.—Prof. ISAIAH BOWMAN of the Department of Geology, Yale University, read this paper. He said that the demand for water was always a serious one in the life of municipalities. Hydrology was consequently reduced to a science.

As a member of the Government Geological Survey, the speaker had made an investigation of the underground water resources of Long Island, which formed part of a special government report. He had found extensive water sources on the south side of the island. The deep-ground water was practically unlimited, the bedrock of Long Island being a continuation of that of the mainland. There was a continuous flow of ground water toward the sea. This flow was carefully measured. Natural underground reservoirs were furnished by impenetrable beds of clay overlaid by fairly coarse gravel, so that wells driven to the clay would serve to tap these reservoirs. Most of the wells would yield permanent and abundant supplies of water. The sand and gravel through which the water had to travel in order to reach the lower levels furnished an efficient filter for all organic impurities. Whatever part of this supply was not available immediately for drinking purposes could be made so by storage in reservoirs either exposed to the sun or possibly supplied with cultures of opposing organisms.

Stated Meeting, Held October 16, 1906.

Dr. W. F. Campbell in the Chair.

Presentation of the Medical Library of the Late Dr. Willard Parker.—Dr. James Peter Warbasse, Directing Librarian, made the address of presentation of this library of 400 volumes, a gift to the Library of the Medical Society of the County of Kings from Dr. Willard Parker of New York City.

The Treatment of Certain Chronic Infectious Processes.—Dr. Lewellys F. Barker, Professor of Medicine, Johns Hopkins University, read this paper. He alluded to the fact that the bacteriologists taught a great deal about the nature of infection and that it was the duty of clinicians to apply this teaching in diagnosis and treatment. The process of infection had been made clear; also how the body entered into competition with lowly organisms in the struggle for existence. This teaching included the mechanisms of defense, the ways in which they were overcome, and the mode of entry of bacteria and protozoa into the body. It was shown that some bacteria entered the body by one door only—the cholera vibrio entering only through the intestinal epithelium; likewise the typhoid bacillus. Other parasites entered by various paths, *e.g.* the staphylococci and streptococci. The period of incubation was the time during which the organisms multiplied until they were numerous enough to have an appreciable effect on the host. This was produced either by the toxins or by the bodies of the microorganisms. Sometimes the invasion was merely local, as in an ordinary boil. Sometimes the bacteria spread by direct continuity, as the extension of the gonococci from the urethra through the prostate, bladder, ureter, to the pelvis of the kidney. Another form of extension was by metastasis, *e.g.* the arthritis and endocarditis secondary to tonsillar infection with streptococci. The rose spots in typhoid were metastatic infections of the skin, containing typhoid bacilli. True septicemia was an expression of a general blood extension of microbic infection, *e.g.* general streptococcus and staphylococcus infections, and quartan malaria. It was remarkable that a certain organism, like the gonococcus, might have a varying behavior, in one case being confined to the urethra, in another extending to the prostate, in another, spreading by metastasis to the heart and joints, or even giving rise to a true gonococcus septicemia. Different bacteria also had different predilections; leprosy had an affinity for the nerve trunks and multiplied in them; the cholera vibrios thrived only in the intestinal epithelium, even when injected into the blood. The gonococci, when inoculated into the blood, chose the susceptible joints. Other bacteria, like the staphylococci, streptococci, and pneumococci, had less limited predilections. The bacteria overcame the mechanisms of defense in various ways by means of toxins, endotoxins, lysins, aggressins, antigens, and the like. The general phenomena of infection were leucocytosis or leucopenia, fever or subnormal temperature, hemorrhagic diathesis, splenic tumor, anemia, general disturbances of nutrition in the organs, parenchymatous degeneration of the kidney, and changes in the nerve-cells. Rather than symptoms of infection, these were to be regarded as biological reactions, taking place in the body during infection. The biological reaction was frequently associated with a subsequent more or less complete immunity. One had to differentiate between the acute and the chronic infections. Typhoid, cholera, plague, pneumonia, and influenza ran usually a very acute course; the patient was either killed or soon recovered. In chronic infections, like tuberculosis, leprosy, and actinomycosis, there was little tendency to spontaneous cure. But the distinction between acute and chronic infections was not a hard-and-fast one. As regards the varieties of biological reactions, it was noted that in antitoxic immunity the body manufactured a substance to neutralize the soluble bacterial poison, as in diphtheria and tetanus. In the majority of infections there was instead an antibacterial immunity, as, in typhoid fever or cholera, the body elaborated substances which prevented the further growth and life of these bacteria. The antibacterial substances were either agglutinins, as evidenced by the Grüber-Durham-Widal reaction, or the bactericidal substances, which actually killed the bacteria, or the bacteriolytic substances which in addition dissolved them. Finally there were the substances recently discovered by Wright of London, which neither killed, clumped, or dissolved the bacteria, but acted upon them in some mysterious way, modifying them in such a manner as to make them suitable food for the leucocytes. They sensitized the bacteria for the leucocytes, and acting as substances that catered to the leucocytes, they were called by Wright "Opsonins." Some infectious processes yielded a permanent immunity after a simple attack had run its course, while others apparently yielded no immunity at all. In diseases like tuberculosis and leprosy, it was hard to find evidences of immunity. Such diseases were apt to last the entire lifetime of an individual. The speaker commended Dr. Rickett's book on "Infection, Immunity, and Serum Therapy" as a valuable exposition of these subjects, giving a clear and succinct account of the newer work. The speaker next discussed the therapeutic measures employed in combating chronic infections and the principles underlying the former. Ever since Hippocrates physicians had been trying to help nature. Gradually a whole series of measures had been found. In all times the principal object was to keep up the strength of the patient, to maintain the natural resources of defense. Bacteriologists had proven that with good food, sufficient sleep, and relief from strain, the mechanical defenses were better, the opsonic index higher, and the bactericidal power of the blood greater. The first therapeutic measure discussed was that of the use of chemical disinfectants. The object was to open up the infected part of the body and wash it out with antiseptics. This method had its uses, but its vogue was getting less and less. Surgeons were relying more on opening up a part and washing it out with substances not chemical disinfectants. This was a fortunate change, for substances, powerful enough to kill bacteria, would also succeed in killing the cells. This was especially true in pyogenic infection. Some chemical disinfectants also destroyed this substances in the blood which had the special function of fighting the bacteria. A minute quantity of lysol in the blood was capable of doing this. The method of surgical extirpation of the infective focus was also not without its dangers. In the presence of a tuberculous joint this was fully realized, and surgeons succeeded best by leaving it alone. Efforts at excision led to diffuse miliary tuberculosis. Moreover, the incision stirred up the infective agent and interfered with nature's powers of resistance. As the result of massage of such a joint the opsonins were diminished in amount. Massage of a tuberculous joint

caused inoculation of the patient, which might poison his body and interfere with its native powers of dealing with the infection. Simple percussion of the chest or having twelve students percuss it might likewise cause a diminution in the amount of opsonins and in the natural resistance. The next therapeutic method alluded to was that of increasing the flow of blood to a part by means of hot fomentations, hot ovens, acute hyperemia, counterirritation, cautery, or sinapisms. The rationale of these procedures was now understood more than formerly. They increased the amount of lymph, blood, and phagocytes in the part, and also the amounts of antitoxic and antibacterial substances. They increased also those sensitizing substances known as opsonins which prepared the bacteria for the phagocytes. In the presence of suppuration poultices were often used. Why did not the infection cure itself? The reason was that the lymph, blood, and leucocytes accumulated to so great an amount that they could not get out. The bacteria used up the antibacterial substances, and no new ones could get in. So the rational procedure was to open up the part, let out the waste, and allow fresh blood and phagocytes to come in and complete the cure. In localized chronic infections massage served to increase the flow of blood, and had the same effect as passive hyperemia. The Bier method of producing the latter consisted in compression. If the wrist joint was involved the veins of the forearm were compressed, allowing the arterial blood to flow to the joint, but preventing the venous blood from getting out. The joint was thus flooded with blood-serum, phagocytes, bacteriolysins, bactericidal substances, and opsonins. In Bier's method there was no easy outflow of the serum until the obstruction was removed. To enhance the value of this method Klapp made an incision into the affected part, after which passive hyperemia was produced. This insured the venous engorgement and increased the lymph formation of Bier's method, and at the same time effected an exit of lymph through the incision, exposing the part to a continuous flow of fresh serum, and its contained protective substances. The next therapeutic method discussed was that of serum therapy. Only two or three sera proved their usefulness; they were the antitoxins for diphtheria, tetanus, and perhaps that of snake-poisoning. The antipneumonic, antistreptococcic, and antityphoid sera, although bactericidal, had practically no antitoxic value. The products of the living activity of these germs were practically harmless, these germs owed their virulence to the endotoxins which were set free when the bacteria died and were broken down. The streptococci, staphylococci, gonococci, typhoid, and cholera germs did not produce soluble toxins in any appreciable quantity, and the symptoms of infection were to be accounted for only by the endotoxins set free when the bacteria died. According to Pfeiffer, the organism did not build antibodies to these endotoxins; there could not be antiendotoxins comparable to the antitoxin of diphtheria. Bactericidal substances might be of value, but if injected into the system they would kill the bacteria, set free the endotoxins, and actually make the patient worse. It had not yet been found possible to produce a serum containing so rich a content in opsonins as to be available for human inoculation. It was found possible to increase the opsonins in horse's serum, but not in sufficient concentration as to make this form of treatment efficacious. There was as yet no knowledge about the other possible antibacterial substances that might help in the production of immunity. Antibacterial sera were as yet disappointing. A method of treatment recently urged by Wright was that of inoculation with the bacteria themselves. The symptoms of tuberculosis were due to the endotoxins set free by the death of the bacilli. It was found that in various forms of tuberculosis, as in tuberculous cervical adenitis and in tuberculous arthritis, there was a lowering of the opsonic power of the blood. Bacterial inoculation produced an increase in the opsonic power. Wright had devised a method of measuring the opsonic index. In cases of tuberculosis in which the opsonic index was high, the body was doing well in the battle and inoculation was unnecessary. The injection of minute quantities of dead tubercle bacilli served to increase the opsonic index in cases in which it was low. It seemed as if in certain chronic tuberculous infections the body was not destroying enough tubercle bacilli to cause the biological reactions which gave rise to the opsonins. By artificially introducing dead tubercle bacilli, the production of opsonins was stimulated so that the body could fight the living tubercle bacilli to better advantage. This was the principle underlying the tuberculin treatment of tuberculosis, as still practised with apparent success at Saranac Lake by Trudeau. The bacterial inoculations were found by Wright to be helpful in the treatment of tuberculous glands and lupus, and in the cure of tuberculous sinuses after operation. The speaker described the method of determining the opsonic index. It consisted in drawing from the patient's finger a little blood, which was diluted with sodium citrate and centrifugalized so as to obtain the white blood corpuscles in a layer. Some of these were mixed with a suspension of tubercle bacilli and the patient's serum. A smear taken from this mixture after it had been kept for half an hour in the thermostat was stained and the number of bacilli ingested by fifty leucocytes was counted. On dividing by fifty this gave the average number of bacteria ingested by each leucocyte. The normal number of bacteria taken up by each leucocyte would represent the index 1.00. Twice that number would give an opsonic index of 2.00. The work of Wright was confirmed by Hektoen of Chicago, by Simon of Baltimore, and Potter of New York. Among the cures effected by Wright's method were tuberculous cystitis and furunculosis. Large doses of bacterial vaccines were harmful in producing a marked diminution in opsonic power. The speaker next alluded to various recurrent metastatic infections having a chronic course, particularly polyarthritis and endocarditis. The majority of the so-called acute and subacute rheumatisms, many of the chronic forms and some of the cases of arthritis deformans were instances of infectious arthritis. The joint infections were due to local foci situated elsewhere. The persistence of the primary focus led to recurrent exacerbations in the joints. In a large percentage of the cases this primary focus was in the palatine tonsils, even though the latter were atrophic. Such local focus might be in the pharyngeal tonsil, or in the gums, as in pyorrhea alveolaris (Rigg's disease). In women the uterine canal or the Fallopian tubes might be the seat of the local infection. Gonorrheal rheumatism was the first of the metastatic arthritides to be recognized. Other local sources of metastatic joint disease were otitis media, or disease of the accessory sinuses of the nose, or even bronchitis, pneumonia, or enteritis. The obvious treatment of these metastatic infections was removal of the local cause. The common endocarditis in young people was strongly suggestive of a primary focus of infection. This view was supported by the analogical rheumatic endocarditis. In many cases the endocarditis was secondary to a tonsillitis. An excision of an hypertrophied tonsil might be the sole means of preventing a recurrence of an endocarditis. In very young children there might be some protective function in the physiological activity of the tonsils connected with an internal secretion. This might make one hesitate to remove the tonsils in them. But in later life this was not to be considered. Even in very young children the removal of the palatine tonsils would leave the lingual tonsil to carry on the function of internal secretion. Acute tonsillitis was to be regarded as a very serious infection on account of its metastatic possibilities, and therefore rest in bed, together with very active therapeutic measures, were to be enforced in order to combat the disease and overcome it in time to prevent metastases. The responsibility for a great deal of polyarthritis, endocarditis, and perhaps acute and chronic nephritis rested upon the shoulders of the general practitioner who failed to remove the local exciting cause.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINERS STATE OF FLORIDA; REGULAR BOARD.

October 17 and 18, 1906.

ANATOMY.

1. Name the bones and ligaments of the ankle joint.
2. What bones form the shoulder?
3. Facial artery—origin, course, and distribution.
4. Define and describe capillary circulation.
5. Mention the salivary glands and their ducts. State where these ducts open.
6. Give the gross anatomy of the stomach.
7. Into what and how far from the pyloric orifice of the stomach does the ductus communis choledochus normally open?
8. Describe the appendix vermiform. Locate McBurney's point for performing appendectomy.
9. What is the pons Varolii, and where situated?
10. Give origin, course, and distribution of median nerve.

PHYSIOLOGY.

1. Describe the normal pulse; state the factors active in its maintenance, and give the rate during infancy, youth, and adult life.
2. Describe a complete physiological revolution of the heart.
3. Give the principal characteristics of gastric juice in man.
4. Describe the phenomena of (a) asphyxia, (b) syncope, (c) sleep.
5. What changes are produced in the air and in the blood by respiration?
6. Define (a) tonic muscular contraction; (b) clonic muscular contraction. Give an example of each.
7. State the function of the anterior spinal nerve roots. How is the function proved?
8. Describe the fetal circulation.
9. What is (a) an efferent nerve, (b) an afferent nerve? Give an example of each.
10. What is the composition of human milk?

SURGERY.

1. Name five forms of bacteria and the surgical disease produced by each.
2. Describe thrombosis and embolism. Give the cause of each.
3. What causes gangrene? Name two varieties. Give treatment.
4. Define suppuration and give the cause. What is an abscess?
5. Define inflammation and name three varieties. Give five cardinal symptoms of inflammation.
6. Give etiology, symptoms, and treatment of iritis.
7. Give the diagnosis and treatment of fracture of the clavicle.
8. What important structures would be divided in an amputation four inches below the knee joint?
9. Give the symptoms of a dislocation of the wrist joint. Method of reduction and treatment.
10. Describe the method of sterilizing the field of operation, the hands of the operator and his assistants, and the instruments for a major surgical operation.

GYNECOLOGY.

1. What is the normal size and position of the uterus?
2. What do you ascertain from a digital examination and what constitutes a complete gynecological examination?
3. Give symptoms and treatment of acute vaginitis.
4. What pathological conditions and symptoms usually follow laceration of the cervix uteri?
5. Give symptoms and treatment of retroversion of the uterus.
6. What is oophoritis, and how could you diagnose it?
7. Give etiology and treatment of salpingitis.
8. Enumerate symptoms of sarcoma of the mammary gland.
9. What are the nervous manifestations of amenorrhea?
10. What is a vesicovaginal fistula, and explain the operation for same.

THERAPEUTICS.

1. Define what you understand to be the therapeutic limit of a drug, taking digitalis for an example.
2. Give the medicinal uses of belladonna, and state from what source it is obtained.
3. Write a prescription for intertrigo in infants.
4. Name the indications for the use of morphia, sulphate, atropia and aconite, and give the physiological doses of each.
5. What remedies would you prescribe to obtain intestinal antisepsis in typhoid fever?
6. Give the physiological action and therapeutic uses of the officinal digestive ferments.
7. Give the officinal name, composition, and therapeutical uses of Lugol's solution.
8. Litharge. Officinal name and medicinal uses.
9. Manganese. Division into groups. The officinal salt most used, and doses of same.
10. Sedatives. Divide into classes, and state upon what conditions may a sedative become a stimulant.

OBSTETRICS.

1. What are the three stages of normal labor?
2. Signs of pregnancy at end of first three months?
3. Define menstruation.
4. Symptoms of extrauterine pregnancy.
5. Mechanism of labor in R. O. A.
6. Management of breasts after delivery.
7. Treatment of puerperal sepsis.
8. Treatment of pregnancy complicated by nephritis.
9. Treatment of eyes of new-born.
10. Give methods of preventing tears of perineum.

CHEMISTRY.

1. Define the terms matter, solids, liquids, gases, and water of crystallization.
2. Name the five gaseous elements.
3. Give the chemical formula of nitric acid, and mention its properties.
4. What metals belong to the arsenic group?
5. Give the usual tests for sugar and albumin in the urine.
6. Describe the method of making tests for the diazo reaction in suspected urine.
7. Give antidote for arsenic poisoning, and how to prepare same.
8. Give antidotes for caustic potash poisoning.
9. Give tests for salts of sodium and potassium.
10. Name the element found in greatest abundance on our earth and mention its properties.

It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINERS, STATE OF FLORIDA; REGULAR BOARD.

October 17 and 18, 1906.

PHYSIOLOGY.

1. The pulse is the impulse conveyed to the column of blood in the arteries by the contraction of the ventricles and the propulsion of more blood into the already full arterial system. The characters of the pulse which are of most importance are its force, frequency, length, rhythm, and tension. It is maintained by the ventricular systole, the elasticity of the arterial walls, and the volume of the blood in the vessels. In infancy the rate is about one hundred and twenty a minute; in youth about eighty-five, and in adult life about seventy.

3. It is a thin, colorless, acid fluid, with specific gravity of about 1.002, and containing from one-half to one per cent. of solids. The average daily amount has been placed anywhere between six and twelve pints. It contains (besides water) hydrochloric acid, pepsin, rennin, mucin, and salts of sodium, potassium, calcium, and magnesium. The pepsin is a proteolytic enzyme which will only act in an acid medium; the rennin coagulates caseinogen.

5. The changes produced in the *air* by respiration are:

	Inspired Air.	Expired Air.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	0.4 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

In the *blood* the changes take place in the capillaries of the lungs, and are: (1) the giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, and (4) it also loses a small amount of watery vapor.

6. In tonic muscular contraction the muscle remains for some time in a state of rigid contraction. In clonic contraction the muscle alternately contracts and relaxes. Tonic muscular contraction occurs in tetanus; clonic, in an ordinary convulsion.

9. Efferent nerves carry impulses away from the nerve centers. Afferent nerves carry impulses to the nerve centers. The motor nerves are efferent; the sensory nerves are afferent.

SURGERY.

1. (1) Streptococcus pyogenes, producing abscess; (2) bacillus tetani, producing tetanus; (3) bacillus anthracis, producing malignant pustule; (4) bacillus tuberculosis, producing tuberculous disease of bones or joints; (5) streptococcus erysipelatis, producing erysipelas.

2. *Cause of thrombosis*: (1) changes in the walls of the blood-vessels, due to the presence of infection or foreign bodies; (2) changes in the blood, whereby its tendency to coagulate is increased; (3) diminished rate of the blood flow, due to weak heart action or obstruction. *Embolism* is generally due to thrombi, but is also caused by fragments of vegetations or atheromatous or calcareous masses from the cardiac valves or the intima of the arteries; other causes are parasites, pieces of new growths, pigment granules, fluid fat, or air.

4. Suppuration is a special form of inflammation, in which the exudate is unusually prolific in cells, and in which pus is found. The cause of suppuration is the invasion of the tissues by pus-producing bacteria, when the said tissues are in a state of lowered vitality or are not capable of withstanding and disposing of the bacteria and their products. An abscess is a circumscribed collection of pus in a newly formed cavity.

8. Skin; fascia; bones, tibia, and fibula; interosseous membrane; muscles, tibialis anticus, tibialis posticus, extensor longus digitorum, extensor proprius hallucis, flexor longus hallucis, flexor longus digitorum, peroneus longus, peroneus brevis, soleus, gastrocnemius, and the tendon of the plantaris; arteries, anterior tibial, posterior tibial, peroneal; veins, the venæ comites of the arteries, external saphenous, internal saphenous; nerves, anterior tibial, posterior tibial, external saphenous, communicans peronei, musculocutaneous.

GYNECOLOGY.

1. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits.

2. From a digital examination can be learned the presence or absence of vaginismus; the size, position, temperature, sensitiveness, moisture, and laxity of the vagina; the presence of foreign bodies, hernia, fissures, or caruncles; the position, form, and consistency of the cervix uteri; lacerations (including position, number, extent, and direction), erosions, growths, or cysts on the cervix; prolapse, displacements, and size and position of the uterus.

A complete gynecological examination would include (1) anamnesis, including family history; personal history, with special reference to menstruation, labors, and miscarriages; and present illness. (2) Examination of the abdomen (and breasts), including inspection, palpation, percussion, auscultation, and mensuration. (3) Inspection of the external genitals. (4) Vaginal examination, digital, bimanual, and with speculum. (5) Bimanual examination of uterus and appendages. (6) Sometimes the sound, or curette, may be required. (7) Chemical and microscopical examination of the urine. (8) Microscopical examination of discharges or uterine scrapings. (9) Rectal examination. (10) Cystoscopic examination and perhaps ureteral catheterization. (11) In case of phantom tumor or pseudocyesis, anesthetization would be required.

4. Hemorrhage, sepsis, hypertrophy, and erosion of cervix, prolapse of uterus, subinvolution, endometritis, cancer, and discase of the tubes and ovaries.

8. According to Gross "a tumor of soft, elastic, apparently fluctuating consistence, which attains the volume of an adult head in a few months, can scarcely be anything else than a small-celled sarcoma. On the whole, the diagnosis is based upon their indolent origin, lobulated outline, rapid increase, large dimensions for the period of their existence, freedom from lympathic involvements, and marked tendency to ulcerate; upon the not infrequent discoloration of skin, enlargement of the subcutaneous veins, and possibly elevation of temperature; upon the suffering which they awaken late in the disease, and upon their greatest frequency after the thirty-fifth year."

9. Hysteria, paresis, tinnitus aurium, perspiration, defective vision, acne, herpes, urticaria, headache, and flashes of heat.

THERAPEUTICS.

3. R. Amyli
Acidi borici.....āā ℥j. Misce.
Signa: Apply as a dusting powder.

5. Guaiacol carbonate, salol, betanaphthol, naphthalin, thymol, carbolic acid, calomel, and corrosive sublimate.

6. Note that only two—pepsin and pancreatin—are officinal.

7. Liquor iodi compositus. Iodine, 5 parts; potassium iodide, 10 parts; and water up to one hundred parts. It is used as a counterirritant and as an alterative; on bruises and sprains, also for pleurisy, synovitis, chronic rheumatism, intercostal neuralgia. It is also used internally, in doses of from one to ten minims, well diluted, for the vomiting of pregnancy, or after anesthetics. It is used, too, as an injection, for goiter, also into the various serous cavities in cases of chronic inflammations.

8. Plumbi oxidum. Used in the manufacture of lead plasters, and of some of the other lead salts, also as the basis of other plasters. It is further used as a protective agent against chafing from splints and other appliances, and to prevent bedsores.

9. Mangani dioxidum præcipitatum, dose four grains; mangani sulphas, dose four grains; mangani hypophosphis, dose three grains; and potassii permanganas, dose one grain.

CHEMISTRY.

1. *Matter* is anything which occupies space. A *solid* is a form of matter in which the relative positions of the molecules are fixed and constant. In a *liquid* the molecules glide past each other and the substance assumes the form of its container. In a *gas* the molecules tend to get away from each other and to occupy a greater space. In a *solid* both volume and form are definite; in a *gas* both volume and form are indefinite; and in a *liquid* the volume is definite but the form is indefinite.

2. Hydrogen, oxygen, nitrogen, fluorine, and chlorine.

3. HNO_3. It is a colorless liquid, with a strong acid taste and reaction. It is a strong oxidizing agent, and dissolves most metals, with the formation of nitrates. With hydrochloric acid, it forms aqua regia, which is capable of dissolving the so-called "noble metals." In damp air it gives off white fumes. When strongly heated it is decomposed into H_2O, N_2O_4 and oxygen.

4. The answer to this question will depend upon the textbook used by the student (or examiner). Witthaus puts arsenic in the same group with nitrogen, phosphorus, and antimony; Remsen, in the same group with nitrogen, phosphorus, antimony, and bismuth; Simon, in the same group with antimony, tin, gold, platinum, and molybdenum; Holland, in the same group with antimony and tin.

6. The reagent is made of two solutions, which should be kept in separate bottles. One is a saturated solution of sulphanilic acid in a mixture of 50 c.c. of hydrochloric acid and 950 c.c. of water. The other is a 0.5 per cent. solution of sodium nitrite. To make the test: 40 c.c. of the sulphanilic acid solution are mixed with 1 c.c. of the sodium nitrite solution, and the mixture is well shaken. Equal quantities of the urine and reagent are then shaken together in a test tube, and upon the surface of this mixture from 1 to 2 c.c. of ammonia are floated. A red band formed at the junction of the liquids implies an affirmative result.

7. Freshly prepared ferric hydroxide, $Fe_2O_6H_6$. The

two following solutions should be kept in separate bottles, and when required should be mixed and administered:

(1) ℞. Liquoris ferri tersulphatis... ℥ij
Aquæ destillatæ ..... ℥vj. M.

(2) ℞. Magnesiæ..... ℥iij
Aquæ destillatæ ..... ℥viij. M.

8. Dilute vinegar, vegetable acids, milk, and neutral oils.

9. *Sodium* colors the Bunsen flame yellow. With periodic acid (HIO_4) in excess, it gives a white precipitate in not too dilute solution. *Potassium* colors the Bunsen flame violet. With periodic acid it gives a white precipitate, sparingly soluble in water, and insoluble in alcohol.

10. Oxygen. A colorless, odorless, tasteless gas, slightly soluble in water. It has a strong tendency to combine with other elements, and forms binary compounds with all elements except fluorine and bromine. Oxygen is necessary to the processes of life and combustion.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	Feb.	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	April	1
Arkansas*	F. T. Murphy, Brinkley	Brinkley	April	9
California	Chas. L. Tisdale, Alameda	San Francisco	April	16
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March	12
Delaware	J. H. Wilson, Dover	Dover	June	18
Dis. of Col'bia	W.C. Woodward, Washington	Washington	April	11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May	15
Georgia	E. R. Anthony, Griffin	Atlanta	April	—
Idaho	J. L. Conant, Jr., Genesee	Boise	April	2
Illinois	J. A. Egan, Springfield	Chicago		
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May	28
Iowa	J. P. Kennedy, Des Moines	Des Moines	March	19
Kansas	T. E. Raines, Concordia	Topeka	Feb.	12
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April	23
Louisiana	F. A. La Rue, 211 Camp St., New Orleans	New Orleans	May	9
Maine	Wm J. Maybury, Saco	Portland	March	5
Maryland	J. McP. Scott, Hagerstown	Baltimore	June	—
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March	12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June	11
Minnesota	O. E. Linier, 24 South Fourth Street, Minneapolis	St. Paul	April	2
Mississippi	J. P. Hunter, Jackson	Jackson	May	14
Missouri	J. A. B. Adcock, Warrensburg	Kansas City		
Montana*	Wm. C. Riddell, Helena	Helena	April	—
Nebraska	Geo. H. Brash, Beatrice	Lincoln	February	13
Nevada	S. L. Lee, Carson City	Carson City	February	4
N. Hamp're*	Henry C. Morrison, State Library, Concord	Concord	January	—
New Jersey	J. W. Bennett, Long Branch	Trenton	June	18
New Mexico	B. D. Black, Las Vegas	Santa Fe	June	3
New York	C.F. Wheelock Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo.	January	29
N. Carolina*	G. T. Sikes, Grissom	Morehead City	May	—
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April	2
Ohio	Geo. H. Matson, Columbus	Columbus	June	11
Oklahoma*	J. W. Baker, Enid	Guthrie	March	26
Oregon*	B. E. Miller, Portland	Portland	April	—
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia Pittsburg,	June	—
Rhode Island	G. T. Swarts, Providence	Providence	April	4
S. Carolina	W. M. Lester, Columbia	Columbia	June	—
S. Dakota	H E. McNutt, Aberdeen	Sioux Falls	July	10
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville,	May	—
Texas	T. T. Jackson, San Antonio	Austin	April	1
Utah*	R. W. Fisher, Salt Lake City.	Salt Lake City.		
Vermont	W. Scott Nay, Underhill	Montpelier		
Virginia	R. S. Martin, Stuart	Lynchburg	June	18
Washington*	C. W. Sharples, Seattle	Spokane	July	2
W. Virginia*	H. A. Barbee, Point Pleasant	Wheeling	April	9
Wisconsin	J. V. Stevens, Jefferson	Madison	July	9
Wyoming	S. B. Miller, Laramie	Cheyenne		

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

A Case of Frozen Feet Treated by Thermaerotherapy.—Francis S. Skiff had under his care a patient whose toes had been frozen. The toes of both feet were lifeless and in half of each foot when pricked with a needle there was little sensation. After treating the feet for three days with hot bichloride packs, the writer turned to local, dry, hot air applications. The patient was made to place his feet in the apparatus at a temperature of 140-150° F., three or four times a day, for from an hour to an hour and a half each time, during a period of two weeks. After two treatments the patient felt better. The feet were finally saved with the exception of a part of the two great toes and the second toe. The after-treatment consisted of antiseptic dressings and irrigations with lysol or carbolic acid solution.—*Archives of Physiological Therapy.*

Surgical Suggestions.

Intussusception.—In discussing this condition Cole says that the records of large numbers of cases show that spontaneous cure occurs in less than 2 per cent. of the cases. The diagnosis is rarely doubtful in infants. Tumor exists in almost all cases. Search for it should be made under anesthesia, and by the conjoined bimanual examination of rectum and abdomen. Sudden onset, paroxysmal pain, vomiting, bloody discharges, absence of fecal matter, and the presence of tumor, leave no doubt for diagnosis even in cases in which the baby is suffering from enterocolitis. Purgatives aggravate the symptoms, and are inadmissible. Attempts at reduction of the invagination by distension of the colon under water pressure should be used only in cases that are of not more than six hours' duration. Irrigation should be performed slowly, thoroughly, and with the greatest care, the baby being anesthetised. The dangers of this treatment are: (*a*) Shock, (*b*) loss of time, (*c*) increase of the constriction, (*d*) rupture of the colon. In every case in which the complete disappearance of the tumor is in doubt, abdominal section should be at once performed.—*Intercolonial Medical Journal.*

Narcosis in Diabetes.—The question of administering anesthetics to diabetic patients is discussed by Kausch, who summarizes his opinions as follows: General anesthesia should be used as seldom as possible in dealing with diabetics, and the various methods of local anesthesia should be resorted to when feasible. Anesthesia for diagnostic purposes alone is to be avoided, as well as repetition of the anesthesia. Ether is always to be preferred to chloroform. The amount of the anesthetic agent and the duration of the anesthesia should be reduced as much as possible, and in order to avoid the production of acetonuria through long fasting it is advisable to operate early in the morning. In order to prevent acidosis every diabetic who is about to be operated on should be given bicarbonate of soda until the urine becomes alkaline. If coma is threatened sodium bicarbonate should be administered vigorously by mouth, by rectum, and intravenously.—*Archiv für klinische Medizin.*

Sterilization of the Hands.—Apropos of the various procedures in use for sterilizing the hands Leedham-Green says that unless the hands are in an exemplary cosmetic condition good results cannot be obtained by any method. A roughened or chapped hand does not admit of disinfection. Even after the most prolonged and energetic washing of the hands in soap and hot water, it is not possible materially to diminish the number of microbes on them, and there is no advantage to be gained by unduly prolonging this washing process, as the hands never become sterile, and, owing to the loosening of the epidermis, generally appear more infected after than before the washing. The use of turpentine, benzoline, or xylol during or after the washing with soap and hot water, or of soaps to which antiseptics had been added, does not appreciably improve the results. The aqueous solutions of carbolic acid, lysol, perchloride, or biniodide of mercury are practically powerless to affect the microorganisms situated on the hands, and the use of these antiseptics after a thorough preliminary washing of the hands utterly fails to render them sterile. The use of a saturated solution of permanganate of potash followed by the application of strong oxalic acid gives wholly inadequate results. Alcohol, owing to its property of hardening and fixing the superficial cells of the epidermis and its marked bactericidal action, possesses a remarkable power of sterilizing the hands, far surpassing that of all other agents. Of all the methods tested, the best results were obtained by the following modification of Fürbringer's process: (*a*) The hands are first scrubbed for five minutes with soap and very hot water (about 50° C.), the water to be frequently changed. The use of sterile sea sand as an addition to the nail-brush is an advantage. (*b*) The hands are then rubbed with methylated spirit for three minutes. (*c*) Afterwards scrubbed for a minute or two with 70 per cent. sublimate-alcohol (1 in 1,000). (*d*) And finally rubbed until dry, and polished with a sterile cloth.—*Birmingham Medical Review.*

A Simple Truss for Children.—An efficient, cheap, and cleanly truss for use in cases of inguinal hernia in infants is described by Fiedler. It consists of an ordinary skein of zephyr wool which is provided at one end with two tapes. The skein is passed about the child's body, and the end having the tapes is slipped through the loop and across the inguinal region between the legs. It is then secured in this position by tying the tapes around the legs. A number of such skeins are kept on hand and washed as often as necessary. The efficiency of the device is increased by placing a small pad over the hernia.—*Zentralblatt für Chirurgie.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 12, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	446	162
Diphtheria	291	51
Measles	204	6
Scarlet Fever	234	8
Smallpox	3	—
Varicella	154	—
Typhoid Fever	43	8
Whooping Cough	60	4
Cerebrospinal Meningitis	21	9
Malarial Fever	... ..	.....
Totals	1456	248

Origin of Urinary Casts.—Alessandro Amato states that hyaline casts arise from fibrinous fibrillary cylinders by the action on them of a special pathological secretion of the cells of the convoluted tubes, which shows itself in the form of droplets which have a strong affinity with basic coloring matters. He believes that this is not the explanation of the genesis of all homogeneous cylinders. They may also be derived from a pathological secretion of the epithelium of the convoluted tubules, which appears in large drops in the tubes. These may be slightly granular, and may be found in the ascending and descending limb of Henle's tube, and in the straight tubules. Granular cylinders arise from protoplasmic detritus derived from changes in the internal border of the epithelial lining of the canaliculi, which gradually empty the cell contents into the lumen of the tubule, leaving the nucleus and the wall of the cell behind. Epithelial casts represent the desquamation of the straight tubes. Waxy casts are derived from the fusion of droplets of a yellow color found in the lumen of the canals, and in the epithelial cells of the convoluted tubules. They may be interpreted as hemoglobin separated from the blood.—*Rivista Critica di Clinica Medica.*

Favorable Effects of the Use of Extract of the Suprarenal Capsules in a Case of Addison's Disease.—P. Spillman and M. Perrin have given careful study to the treatment of Addison's disease. They refer to the results of various authorities who have been interested in this same subject. Adrenalin has been employed sometimes with success. This success, however, has been far more rare than in cases in which the total extract of the suprarenal capsules has been used. Adrenalin is only one part of the suprarenal capsules, and does not offer a complete substitute when the destruction of these organs is excessive. In certain cases even when the entire extract has been used no result has been obtained. It must be accepted that the alteration of the suprarenal capsules is only one part of the disorder; there are lesions of the solar plexus, and there is also tuberculosis of other organs, the course of which must be considered a most important element in the prognosis. The writers then refer to a patient, a man forty-two years old, whom they have treated with suprarenal extract by means of injections with excellent results. It is necessary to repeat the treatment from time to time. But even with these limitations these investigators are satisfied with the effect of the drug as employed in this case.—*Revue Française de Médecine et de Chirurgie.*

Acidification of the Viscera as a Certain Sign of Death.—Brissemoret and Ambard have made researches in this subject. In the living animal the liver and the spleen have an alkaline reaction, but some time after death these same organs show a progressively increasing acid reaction. The acidification of the viscera may be a valuable sign of death, because the acid reaction occurs rapidly after death, because it is an absolutely constant phenomenon, and because it is easy to prove. In order to make the experiment one makes use of litmus paper and a fine needle mounted on a syringe. As the liver and spleen both become very rapidly acid after death, one may puncture either of these organs. A little of the visceral pulp and a little blood are extracted in the lumen of the needle. The conclusions of these investigators have been confirmed by the work of Ascarelli, who has conducted his researches in relation to both man and the lower animals. Acidification is more or less rapid, according to the cause of death, and it is more rapid after death from hemorrhage (7 to 12 minutes) than after death from asphyxia (18 to 28 minutes). This condition does not appear at the same time in the different organs. The spleen is the first to show evidence of it; the liver, the lungs, the kidney, and the heart follow in order. In the muscles the development of the acid reaction is tardy and is related to rigor mortis. Nevertheless, in certain cases, muscular fatigue and strychnine poisoning, the acidity of the muscular tissues may exist before death. The determination of visceral acidity constitutes the first certain sign of death, a sign which is simple and easy to determine in routine practice. —*La Tribune Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 11, 1907:

SMALLPOX—UNITED STATES.

REMINISCENCES OF MEDICAL PRACTITIONERS IN NEW YORK DURING THE PERIOD OF THE EARLY HISTORY OF THE ACADEMY.*

By A. JACOBI, M.D., LL.D.,

NEW YORK.

The New York Academy of Medicine was founded in 1847, sixty years ago, by one hundred and eighty-four physicians. Two of those are still alive; one, is Nicholas Lafayette Campbell; he resigned 1849. I. C. Hepburn, a graduate of the University of Pennsylvania, has continued his membership since April 1, 1863, as a nonresident. He lives at 71 Glenwood avenue, East Orange, N. J.

These sixty years correspond with the existence of modern medicine established on two solid pillars, viz., sound and repeated clinical observation, and anatomical, local, histo- and bacteriological, and biochemical diagnosis. The rapid progress of medicine during this time in the United States is best explained by the unprejudiced blending of cool Anglo-Saxon empiricism with the readily adopted anatomical, pathological, and general laboratory work. You understand that I speak of that privileged part of the profession which is no longer where we stood sixty or more years ago, when the words: paralysis, spinal irritation, dropsy, hydrocephalus, lung fever, continued fever, cyanosis, idiocy, convulsion, were taken or offered as full-fledged diagnoses, or when the principal etiological factors were colds, worms, and teeth, and the therapeutic refuge calomel.

The study of the discourses before the stated meetings of the New York Academy of Medicine and the gatherings of the best men of the profession will pay you. That is why I want you to look at least over the two first volumes of our Transactions and the two first volumes of the Bulletin. They were published nearly half a century ago. By so doing you will learn that many of the men who participated at a mature age in whatever came up for general consideration were those who will uphold our American fame for all times. It appears when they grew older they became more impressed with their responsibility to the profession. John Watson, Alonzo Clark, Fordyce Barker, J. Marion Sims, Gurdon Buck, James M. Minor, Ernst Krackowizer, John H. Griscom, and many more were always present, and gave their best. They discussed diphtheria, tracheotomy, sudden death during labor, albuminuria, fracture of the thigh, moral insanity, epilepsy, hip joint disease, the eternal milk question, public health, pulmonary tuberculosis, human monstrosities, cyanosis, alcoholic stimulants, anesthetics, cerebrospinal meningitis, hematocele, lunacy legislation. Some of you may find, when perusing these papers and discussions, that several things which had to be discovered and rediscovered by persons ignorant of our medical history, may be read with ease and profit in those old volumes. I may also assure you that in those distant times only very advanced age and sickliness were reasons for staying away. The interest in the Academy and the profession exhibited by our old colleagues did not die out with the termination of presidential and other offices. To us, the young men of that time, many of them seemed like gods and demigods, but not, like them, invisible. They remained with us. White hair and bald heads were always seen in our meetings, and we young men were gladdened by their presence and the instruction gathered from their lips.

My memory recalls, however, some proofs that they were not all angels. Some of them knew it all, like, in our days, a hospital junior, and could not be converted, though it is true that the majority were anxious for any supply of learning or information near at hand or from afar. I may have to speak of the ignominious treatment dealt out to Horace Green, within my hearing, though before my membership, by the majority of a committee appointed for the purpose of looking into his local treatment of the larynx and trachea. Nor was it possible to keep the hatred and jealousy of the Civil War out of this Academy. T. G. Thomas, a Southerner, was charged with harboring Southern proclivities within his bosom and giving expression to them. He was the recording secretary, and the first year of the war was the last of his secretaryship. I think I am quite correct—for it is only forty-six years ago that it happened—when I state that he had only two votes in his favor, those of two abolitionists of foreign extraction. It is surely true that there are no blinder tyrants, nor greater enemies of public welfare, than the prejudices of race, religion, and politics.

Of my own time there are but few survivors. Stephen Smith joined 1855, Thomas Addis Emmet 1856; he writes history, and is happy in such, as he made himself; Dr. Mark Blumenthal, who at present enjoys his honeymoon, in 1857; Ellsworth Eliot in 1858. Him I should be tempted to call venerable if he had not succeeded in remaining young through the aid of his eternally youthful enthusiasm, fired by the study of the history of American medical, municipal, and social lore.

Having been permitted to indulge in personal reminiscences, I thought I could not entertain you better than by refreshing your memory through call-

*Read in part at the annual meeting of the New York Academy of Medicine, January 3, 1907. Not all of these sketches could be read in this meeting for want of time. They are here printed at the suggestion of the Editor. Many more memories should be revived from time to time, for the number of great and good and warm-hearted men who once were fellows of the New York Academy of Medicine cannot easily be exhausted. They are still active, like the light and warmth of the sun after it has descended below the horizon. Of the biographical notes many are taken from old numbers of the *Medical Register*.

ing up names that should be dear to every American medical man. What warmth and enlightenment there are in history are best represented by biographies. The first president under whom I served was Valentine Mott, the excellent sketch of whose life has just been read by Dr. Smith. His name is familiar to everyone. He was president in 1849 and in 1857, when I joined the Academy. The history of his life may be studied to advantage by every medical man who is desirous of learning about and of appreciating the difficulties of medical study and teaching in bygone times. He died on April 26, 1865, nearly eighty years old. My personal intercourse with him was not exactly intimate, but he was prominent among the old and grand men that took kindly to the young foreigner who, if nothing else, was willing to learn and anxious to work. That is why I could not understand the cruel treatment Horace Green experienced at his hands. Mott was always active, always interested. Such vanity as he had I never had reason to feel to any disagreeable extent. He did not object to speaking of his surgical triumphs, but was more proud of his labors in the dissecting room. Once he asked me on the sidewalk in Fourth avenue: "Have you ever seen a double cremaster?" I looked puzzled. He laughed merrily and said: "I think nobody has," took me by the collar to his house in Gramercy Park, and there in a jar, lo and behold, there was "his" double cremaster.

His successor in the presidency was John Putnam Batchelder, born in New Hampshire, August 6, 1784. He died in New York, April 7, 1868. After having practised medicine on a license he took his degree in Harvard 1815. The last twenty-five years of his life he practised in New York, where he was the president of the Academy of Medicine in 1858. In 1817 he took the chair of anatomy in Castleton, Vt., afterwards that of surgical anatomy in Pittsfield, Mass. Of those early times he would often tell me of the scarcity of bodies, of the expeditions undertaken on the worst moonless nights to distant cemeteries, quite frequently armed, always prepared for traps and scuffles, and hairbreadth escapes. Smilingly he would say, with a twinkle in his eyes: "I was young then, and not at all stiff as you see me to-day." He became widely known by his operations on tumors, on stone in the bladder 1818, ligature of the carotid 1825, for sarcoma of the maxilla, which operation had to be followed by the removal of the maxilla (the first after Valentine Mott), 1832 removal of the upper jaw. If not the first, he was one of the first to remove the head of the femur. He wrote on inflammation, compressed sponge, cholera, and "thoughts on the connection of life, mind and matter in respect to education." That shows the variety of his interests. He never ceased to work and keep his eyes open. He tried to learn from his peers and his inferiors. When I was in Amity street after 1858, I had the good luck to live in his neighborhood. Very often he would come in with a specimen in whose histological structure he was interested. I never met with a man who was more enthusiastic over Virchow's cellular pathology, which he studied in Chance's translation of 1861.

John Hoskins Griscom was born on August 13, 1809, in New York, and died April 28, 1874. He studied medicine in Rutgers College and the University of Pennsylvania, took his degree 1832, was professor of chemistry in the College of Pharmacy from 1836 to 1838, 1842 city inspector, and as such the head of the Health Department, and later attending physician to New York Hospital. City inspector he was a single year only, for the stepfathers of the town wanted a pliable and ignorant political tool. When in the Health Department he ruled that no burial could take place without a permit, the permit depending on a medical certificate. If you consider that New York had at that time nearly half a million of inhabitants—that meant a very large city—you will estimate the low state of our civilization only sixty years ago. Griscom's labors in favor of executing principles of sanitation remained inefficient before the legislature passed the first health laws suggested by him. In the three years following January, 1848, when he was Commissioner of Emigration, 700,000 emigrants landed on our shore. Twenty thousand had ship fever, and Dr. Griscom caught it. His memorial, exposing the hardships of emigrants due to the lack of food and accommodations, overcrowding in steerage, absence of medical care, cruelty of captains, brutality of sailors toward men, and still more toward women, and the indolence of our laws and lawgivers, was a State paper of great value, and certainly contributed to open the eyes of the public, if not the hearts of the legislature. Fifteen years he was a member of the prison association, and ten years the chairman of its executive committee. Many laws ameliorating the fate of the prison inmates are due to his initiative. In this Academy he was seen very often, never without a contribution, never without exerting a great influence, both on account of the value of his words and of his impressive presence, and often passionate bearing. He spoke best when his warm heart was full, and warm and full it always was. If every generation had many men of his stamp, with complete mastery of the subjects he was interested in, a clear understanding of what was wanting in our public affairs, a generous heart which made him offer his labor unstintedly in the public service, the community would be better off, and the profession stand as high in the estimation of the thinking part of the public, as in that of many of the sages of antiquity and modern times.

William Currie Roberts, born in London, 1810, emigrated to New York 1820, graduated at the College of Physicians and Surgeons 1832, founded 1835 the first infirmary for the diseases of women and children (in 361 Broome street), which had soon to be closed on account of lack of funds, started a class for women and children, and nervous diseases in the Northern Dispensary in 1844, was afterwards physician to the city prison and to the Park police. In the third year of the Civil War, 1864, he was an enrollment officer. Much money was made at that time—not by him; the cowards, the tradesmen, the sympathizers with the rebellion paid heavily for being permitted to stay at home, or for not furnishing a substitute—not to him; the love of country came second to that of the bargain counter or of the shoddy factory; graft was the shibboleth—not to Roberts. He died poor, and the well-to-do persons called him "a fool." In the profession he was highly esteemed for his scientific attainments, his frequent contributions to the discussions of the Academy, his probity, aye for his occasional ebullitions of temper always, however, exhibited in the cause of right and justice.

Dr. John W. Francis was born 1789, when Washington was inaugurated in the city of New York as our first President, and died on the 8th of February, 1861, a few weeks before the attack on Fort Sumter. Perhaps some of my readers who were born before yesterday may remember when and what that was. So his life is of exactly

the duration of the first great period of our national existence. In the history of the nation in its social and political development, in its incipient literature, not only medical, he took the warmest interest. He was a keen-eyed, warm-hearted, plain-spoken, and generous-minded man, a practitioner of wide repute, and the consultant of the greatest authority, not only in obstetrics, to which he gave special attention; and for a number of years a teacher of the institutes of medicine, or of materia medica, of medical jurisprudence, and of obstetrics and forensic medicine in the Rutgers Medical College and in the College of Physicians and Surgeons, of which he had been the first graduate. You must not smile at the multiplicity of chairs he filled in a dozen years and of things he taught. You must not forget that this took place nearly a hundred years ago, that the limits of knowledge were narrower than to-day, that the great men in the profession had spent all their lives studying classics, history, and medicine, and its adjuvants, and that there was no specialism of nowadays. Not a half a hundred years before Francis it was considered natural that a profound mind and studious worker could be both a great medical man and a thorough philologist; not thirty years before Francis, Albrecht von Haller taught anatomy, physiology, botany, and the practice of medicine, and was the examiner in surgery, though he never performed an operation. Nor should we, in the America of the twentieth century, be too generous with our ridiculing smiles. Many of us know that within our own time, within a score of years, men would teach in our own colleges, willingly or unwillingly, physiology, materia medica, and surgery, or materia medica, physiology, and obstetrics. Let us fervently hope that medicine will, for the future, get the better of politics and money, or social influences in our schools, and that this future may arrive soon, while some of us may still enjoy that felicity.

Dr. Francis' sojourn in Paris, London, and Edinburgh brought him into connection with eminent men, such as Cuvier, Gall, Gregory, Playfair, Brewster, and many others. His library and artistic tastes kept him in constant contact with professional men of all kinds. That is why very few men whom I knew in the profession of New York could at any time compare with him in mental breadth and vigor. He was very social when you knew him more intimately, and inclined to be jocose. I had seen him a few times only, when one day he stopped me at the corner of Broadway and Bond street, near where he lived. "They speak well of you," he said, "and you will get on; only people want sometimes some outward show. Now, I am an old man, and you will not mind it when I say you ought to have another tailor." I replied: "You see, Dr. Francis, you are an old doctor, and famous, and you can afford to wear the old-fashioned clothing of the eighteenth of Brumaire and of the century of William Penn, but I cannot afford yet a better tailor." He laughed, took me to his office, and we had a pleasant half hour, at least I, for he tried to make me believe that I taught him something of medical doings in Germany, with which he said he was not so well acquainted as with the affairs of Great Britain and France. My remarks on his clothing appeared rather to please than to shock him. He was somewhat inclined to be a little pompous, and the cut of his clothing was fashionable when he was a boy. Otherwise his mental outfit and the breadth of his knowledge, and manifoldness of interests, and wide general horizon have often reminded me in after years of our friend, William H. Draper, who had all the accomplishments of Francis, perhaps some more, but without vanity, and with an undisturbed temper and unruffled, kind-hearted geniality, all of which outlasted his health. Draper was to the end of his days, with the exception of Ernst Krackowizer*, who was his equal, the finest specimen of a thoroughly cultured medical gentleman of his generation.

Under Dr. Hosack he took part in the editing of the *American Medical and Philosophical Register*, and with Beck and Dyckman, of the *New York Medical and Surgical Journal*. "On the Use of Mercury" was published 1811, "Some Morbid Anatomy Descriptions" 1814, his edition of "Denman's Practice of Midwifery" 1825, "Letter on Cholera Asphyxia" 1832. The history of New York was published 1866.

At the age of sixty-five years, there died in 1864 James Stewart. In him I was very much interested, on account of his exertions in the interest of sick children. In 1839 he translated Billard's diseases of children, in 1841 he published a "Practical Treatise," in 1852 "A Few Remarks About Sick Children in New York, and the Necessity of a Hospital for Them, By Philopoedes, an ex-Dispensary Doctor," in 1857 the Academy of Medicine prize "Essay on Cholera Infantum," and was busy in collecting a fund to establish Christ's Hospital for Sick Children. In an obituary he was called "retiring and thoughtful, yet humorous." The first was certainly true; the latter he may have been when I once left his house in Abingdon Square. It happened this way. I was very anxious to make his acquaintance, and told him so when I called upon him without any other introduction than my assertion that I was interested in diseases of children, and desired very much to have him cooperate, or rather lead in the establishment of a children's section in the Academy. Indeed he was "retiring;" my visit was a very brief one; I was chilled all through. I see myself still sitting down on one of the stoops in his block pondering over my misdeeds and what sin I might have committed. I must have risen after a while, but I am pondering yet.

In regard to my pediatric efforts, I was more fortunate when I approached a younger man, Mortimer G. Porter, who died November 24, 1863, of typhoid fever, at the age of thirty-seven years. He aided me in the attempt at establishing a section for the diseases of children in the New York Academy of Medicine. Either the time, or we, were not matured for that achievement. It took twenty-five more years to consummate what we then planned. Meanwhile a similar section was established in the A. M. A. Its first meeting was held at Richmond with the cooperation of Samuel Busey of Washington, whose interest in all subjects connected with medicine and the welfare of the medical profession should always be remembered. I cannot sufficiently extol the interest and labor bestowed on the perfection of our plans by Dr. T. M. Rotch, at that time not so famous, but quite as active as to-day.

Another young man who died much too soon was William Rice Donaghe. He was born in New Haven, Conn., 1830, and died in the Bloomingdale Asylum after a long illness. I knew him well. A year after I tried my feeble strength in the spring course of 1857 of the College of Physicians and Surgeons, he and T. Gaillard Thomas arranged private courses in anatomy and obstetrics at 104 Third avenue. They insisted at that, for us, early time on practical work; dissection and the applica-

*Unfortunately, to the eternal detriment of the profession and the community, Krackowizer died as early as 1875.

tion of the forceps were taught, and their school was successful. He was a manly, tall, blond, long-haired man, with a pale, fearless face, and upright and outspoken, sometimes, as a few thought, too much so. When he was taken sick, some said "I told you so." But it need not be insanity that makes a manly man outspoken, fearless, and pounding away when he is right.

Dr. George Thomson Elliott was born May 11, 1827, and died on the 28th day of January, 1871. After graduating in the University Medical College in 1849 he spent three years in Edinburgh, Dublin, London, and Paris, worked in the lying-in-hospital from 1852 to 1854, and was one of the founders of the Nursery and Child's Hospital. With the Infant Hospital on Randall's Island and the New York Woman's State Hospital he was connected at an early time. He taught anatomy at Woodstock in 1856, and was one of the founders of the Bellevue Hospital Medical College in 1861. He missed a great chance, when the new school was established, in not daring to insist upon at least a three years' course and a shorter vacation. I had for some time been connected with the New York Medical College in East Thirteenth street, and knew the shortcomings of our college methods from my own observation. Perhaps he was too much bent on pleasing, for he was genial, amiable, and sociable, to exhibit the courage of a reformer, or even a revolutionist. In a large general practice, which was promoted by his social connections, his general achievements, and his knowledge of French and Spanish, and by extensive obstetrical and gynecological work, he exhausted himself and fell an early victim to apoplexy. He was the first to be in possession of the hypodermic syringe invented in Paris by Pravaz, 1831, for the purpose of injecting chloride of iron into aneurysms, and introduced into Edinburgh, 1858, by Alexander Wood through a pamphlet entitled: "On a New Method of Introducing Medicine Into the System More Especially Applicable to Painful Local Nervous Affections." In the summer of 1858 Elliott visited that city, and carried with him to America some of the valuable instruments. He gave me of his bounty. I need not say that after they once entered America they were soon generally known among us. You may wonder why it took years before one of the most useful inventions crossed the ocean. Still, fifty years ago it was big and vast. Elliott's "Obstetric Clinic" was published in 1868; it proved a vast improvement on similar previous works, and spread his reputation over the States. The book was preceded and followed by a number of magazine articles. He was always diligent, studious, zealous, and withal gracious. He should be remembered as a man of taste, a refined scholar, an amiable colleague, and should not be forgotten in this, our fast-living time. His linguistic advantages, as I said, were many, but not quite so varied as he thought. Once he returned from Germany and France, and hailed me with the exclamation: "I know German." I requested him to tell me something in German. He posed and said: "Kellner, eine Flasche Markobrunner." I laughed, and asked him to say something else. "Don't ask me too much," he replied. "I had only a few weeks and a great deal of practical work to do, but I do know something else." "What is it?" "Kellner, noch eine Flasche Markobrunner."

James Livingston Brown was born April 2, 1831. He furnishes an example of a typical American career, cut short by death. He attended the public school, was a pupil in a private school in Canal street, and paid his fee by serving as janitor. He began early to teach Latin, Greek, and the rudiments of music. He had a scholarship in Columbia College, received his B.A. in 1852, and A.M. in 1868. In his vacations he would peddle thermometers, pens, and what not in New York, Albany, Boston, and Philadelphia. Add to this indefatigability and ambition, amiable manners, and great personal charm and modesty, together with the idealistic tendency not only to become prominent but also useful, and you have the picture of what makes a great doctor and a good citizen. After his graduation in 1856 in the University Medical College, Dr. Brown soon rose in the opinion of the profession, if not in riches—for it was not his love of music alone that made him retain his place as organist in St. Luke's Church fully seventeen years. He was long connected with Demilt Dispensary, with the Health Department as a sanitary inspector, and with Professor G. T. Thomas as his chief of clinic. His practical work turned more and more to be gynecological, and his contributions to literature belonged mostly to that specialty. Few may have known that the case of diabetes in a baby of less than two years, described in the first volume of the *Journal of Obstetrics and Diseases of Women and Children*, 1869, occurred in his own child. That was one of the accidents occurring in a life full of hardships, exertions, and incipient successes only, which promised so much and was cut off too soon.

David Meredith Reese died March 13, 1861, after having occupied the chair of the Practice of Medicine in the New York Medical College for several years. Born 1800 in Maryland, he graduated from the Medical University of Maryland 1819, and became a vaccinating physician in Baltimore 1824. He was professor in Castleton 1841-42, in the Washington University of Baltimore 1842-45, then in Albany, N. Y. Afterwards he became resident physician of Bellevue, New York, and one of the founders of this Academy in 1847. Cordell, in the medical annals of Maryland, speaks of him as an extensive writer on yellow fever. In 1844 he published an American edition of Cooper's dictionary of practical surgery, and edited until his death, which occurred in New York, May 13, 1861, the *American Medical Gazette*. Being his colleague in the New York Medical College, I knew him well. He was a queer mixture of Southern humor and dyspeptic grimness, a hard worker, and open to scientific suggestions, no matter whence they came. He was older than most of his colleagues, but the small hours of the night never frightened him homewards from the northwest corner of University place and Eleventh street. His anxious life companion blamed us for his early death.

Dr. Richard J. O'Sullivan was born in Ireland, 1833, and died in New York May 16, 1896. He read a paper on school hygiene before the New York Academy of Medicine June 19, 1873. He was sanitary superintendent of the Board of Health, and for some years sanitary school inspector, until the office was abolished. One of the results accomplished by him was this: that of 40,000 children vaccinated by him not one was taken with smallpox during an epidemic of that superfluous, preventable, nasty disease of medieval semicivilization, the pet of antivaccinationists. That is what he did, and many more things. In appreciation of his merits, the Board of Education rewarded him by abolishing the office of sanitary school inspector. In his paper, which was discussed by C. R. Agnew, A. Jacobi, and John C. Peters, he claimed equal rights for physical and mental culture, censured the iniquitous

habit of sending children to school prematurely—he found children of four years in the public classes—and claimed that "seven years is an early enough age for a child to be sent to school." That is the same conclusion I arrived at in my contributions to Gerhardt's "Handbuch," 1876, and to Buck's "Hygiene," and which, fortified by further studies, I am prepared to uphold at the present time. He insisted upon a proper division of time in schools, short lessons, and long recesses, mainly for the very young. Perhaps you are aware of the circumstance that, within a few months this last year, when the question of the shortening of the school hours was discussed by the authorities, it was proposed to insist upon an uninterrupted instruction of the unfortunate young victims through three full hours in succession. If there is a more direct method of raising a nation of invalids and idiots, I am not acquainted with it. O'Sullivan rejected the drill-sergeant exercises and demanded spontaneous sports and amusements during the recesses, objected to insensate cramming, recommended measures for the protection of the eyes, and for ventilation of the classrooms and against the dissemination of contagious diseases. What happened? Dr. Ellsworth Eliot, president of the County Society; Dr. Austin Flint, president of the New York Academy of Medicine; Dr. John C. Peters of the Journal Association, and a number of others, memorialized the Board of Education in behalf of the reappointment of Dr. O'Sullivan as sanitary school inspector on April 12, 1873, the MEDICAL RECORD of September 15, 1873, and the *Evening Post* took an able part in the discussion, all to no purpose. Thus the office created on January 1, 1871, was on April 30, 1873, abolished by the Board of Uneducation. Please to remember that Dr. O'Sullivan worked and wrote for medical school inspection more than one-third of a century ago, both as a member of the Academy and of the medical society of the county, and as a conscientious citizen of the Commonwealth.

John C. Peters was born on the 6th day of July, 1819, in Long Island, and died on the 21st day of October, 1893. As a child he lived in Varick street, as a boy in Bethlehem, Pa. He studied medicine in Berlin, Vienna, and Leipzig. In the minutes of the stated meeting of November 14, 1842, his name appears for the first time in connection with the Medical Society of the County of New York. It was resolved that his examination before the Comitia Minora be sustained, and that he receive a license entitling him to practise physic and surgery. Of the same society he was president in 1866 and 1867, after Henry B. Sands and before Freeman T. Bumstead, George T. Elliott, and myself. The example of a relative who was an influential homeopathic physician in the city of New York, prevailed upon the young, inexperienced doctor to join homeopathy. His social connections with many of the prominent families of the city who partook of the sectarian infection which had spread rapidly on account of the persecution from which the homeopaths had to suffer at the hands of the regulars—a shortsighted and suicidal policy—secured for the cultured, witty, and refined newcomer an extensive and lucrative practice. During that period of his life he began his literary career. Between 1853 and 1856 he published books and pamphlets on apoplexy, headache, diseases of the eye, on married females, on the brain and nerves. They were in part original, in part adaptations of the writings of Rückert, a German homeopathist, and every one of them homeopathic. His paper on "Materia Medica" written from 1856-1860 bore the same stamp. For years he was the chief editor of the *North American Journal of Homeopathy*, the author of several works on homeopathic practice, and the leader, or surely one of the leaders, of what at that time was called a school. You may be able to appreciate the surprise both of friends and foes, when, on August 17, 1861, he published in the *American Medical Times*, then the most influential weekly of the United States, his renunciation of homeopathy. Many hands were raised against him, many armed with clubs. One of the most ethical of our brethren, fed on the dogmatic rule of the code of ethics of the American Medical Association which prohibits newspaper advertising, declared he would not be satisfied until Dr. Peters would publish his renunciation in the daily papers. But he himself remained anonymous, like other cowards. That no friend was left to John C. Peters among his homeopathic colleagues is self-understood. But such was the character of that staunch and steadfast man that neither the suspicion of what was the regular profession, nor the enmity of his associates, nor the loss of a lucrative practice, swerved him from what to him was the plain duty of a scholar, a man, and a gentleman. He survived enmity, however, jealousy, and pecuniary injury, and enjoyed to his last days the profound respect of the profession. He was, 1844, one of the founders of, and an earnest worker in the New York Pathological Society, and for years the editor of its proceedings, but was forced to resign on account of his homeopathic connections. He was one of the founders and presidents of the Medical Library and Journal Association, which contributed so much to the greatness of the library of the New York Academy of Medicine by the donation of all its books and journals. He exhibited a great and important interest in infectious diseases, mostly in Asiatic cholera, on which he began to write in 1860. Almost every year thereafter he added to its literature up to 1873, and again in 1885. His main work, of a thousand pages, was published by Congress in 1873. For the Health Board of New York he studied and wrote on yellow fever in 1878. As he was a believer in the filth origin of infectious fevers, it came natural to him to adopt, when the time matured, the bacteric etiology. I knew him well; that is why I want you to know him, and to remember his name and doings. He was learned, had a general broad, classical, and modern education, and extensive reading. To the last hours an earnest student, a facile and fluent writer, witty and sarcastic, but mostly of a kind humor, and respectful. His temper would sometimes get the better of him, but, as a rule, he controlled it, for he was just to everybody and loyal to his friends. Best of all, he was fearless, as is shown by his renegation of what then was called homeopathy, and a good citizen, ever active in medical affairs, and devoted to the interests of the profession. One side of his character and doings is well illustrated by the following letter, which appeared in the *Evening Post* many years ago. It reads as follows:

"TO THE EDITOR OF THE EVENING POST:

"SIR:—It is interesting (and not least so to those who worked in the Sanitary Commission towards the assuagement of the inevitable horrors of civil conflict) to hear anything authentic in illustration of what Miss Wormeley calls 'the other side of the war;' and such reminiscences are still more worthy of record if they tend to harmonize, for current uses, the feelings of those who, though once in deadly array against each other, ought now, for

their mutual good and for the advance of general civilization, to meet in purely fraternal relations.

"I repeated last night to a sister of Dr. Peters what I had read an hour or two before in your issue of yesterday evening about his refusing a fee from a Union soldier for professional services rendered during the war, whereupon she told me this: Dr. Peters was in the habit of attending, without charge, those soldiers needing medical attendance who were quartered during the conflict at Camp Scott, on Staten Island. When Mobile was taken by the Union forces, the house belonging to one of Dr. Peters' friends—deserted by all its residents but one negro—was entered, as lawful prey, according to the ethics of warfare in an enemy's country, by the bluecoats, consisting mainly, in this instance, of a contingent from Camp Scott, and the faithful servant was, of course, powerless to stop the looting they immediately began.

"But among the decorations of the walls was a portrait of Dr. Peters. This discovery changed the situation. 'Boys!' cried the leader of the Camp Scott men, after some explanations from the old negro, 'here's the doctor's portrait. We can't touch this house. It belongs to one of his kin. Let's skip, and try somewhere else.' And undespoiled it was accordingly left to the old caretaker, his friends reaping where Dr. Peters had sown.

"A. J. Bloor."

The two last named men died within a dozen years ago. Very few of you, however, remember their labors, even their names, for what Sir Thomas Browne said three hundred years ago is surely true: "The iniquity of oblivion blindly scattereth her poppy, and deals with the memory of men without distinction to merit of perpetuity." Thus it happens that otherwise good and true men forget the benefactors within their own ranks, that the men, who by accident or push, are able to arrogate high places, are remembered, and the memory of the modest, consistent, warm-hearted, far-seeing, and altruistic is buried with their caskets.

I wish I could contribute to changing all that.

THE HOUSE FLY AND ITS CONNECTION WITH DISEASE DISSEMINATION.

By G. K. Dickinson, M.D.,

Jersey City, N. J.

The channels by which disease germs are carried is a matter much discussed by the profession and the laity. This question has been answered by superstition and plausible ignorance for ages. Agents, at one time believed noxious, have become practically ignored. It behooves the physician and the sanitarian to investigate carefully and scientifically such means of dissemination as seem potent. The mental attitude of the profession towards flies as an important agent in the spread of disease has been one of credulity and indifference. The object of this paper is to present this question in its several aspects, quoting only those authorities whose statements are the result of careful observation and experimental investigation.

Seven different varieties of flies are found in our houses, 98 per cent. of which is the common house fly (*Musca domestica*). Born in manure, generally that of the horse, or in decomposing matter of any kind, vegetable as well as animal, they enter our homes to alight on foods there stored. Their tastes are indelicate and omnivorous; they subsist on sputum, fecal juices, and the slime and dirt that sticks to exposed surfaces.

House flies are without stings, and are unable to penetrate the skin. Their proboscides, through which they feed, are connected with an extremely active salivary gland, capable of pouring out a large quantity of saliva, which the fly projects against a dry surface, swallowing the subsequent solution. Naturally, solid particles, living organisms, parasites, and eggs, small enough, may pass into this digestive tube. Bacilli of different types and eggs of the nematodes have been observed in the proboscides, stomach, intestinal tract, and defecations. The time that particles remain in the digestive tract of the fly is from 12 hours to 23 days. Evidently the digestive secretions are not active for harm, as organisms will not only pass through alive, but increase in number while in transit. There must be some absorption of the toxins of bacilli, for flies die in large numbers which have had the fortune to imbibe such bacilli as those of the plague and anthrax. Flies are large breeders, lay their eggs by preference in horse manure, but also in decaying meat, meat broth, cut melons, dead animals, and even in cuspidors. On these substances their larvæ subsist until they hatch. From 10 days to 2 weeks after the time the egg has been laid the fly is fully hatched. It is estimated that one fly, laying 120 eggs at a time, will have a progeny amounting up to the sextillions at the end of the season. Busck[15] took a quarter of a pound of horse manure and found in it 100 larvæ and 146 pupæ. This would make about 1,200 house flies to a pound of manure. In a cubic inch of manure taken two inches below the surface 200 pupæ were found.

Caldwell,[41] noting fly larvæ in countless numbers in refuse which had been buried 3 days, questioned as to what became of the flies when the pupæ were hatched deep in the ground, where, after careful search, but one dead fly was found. He made experiments to solve this problem, taking earth and night soil from the trenches, putting it in a glass box, the top of the box being covered with muslin carefully fastened down with gummed paper. The soil and earth were carefully arranged so as to form an imitation of a shallow trench. On the fourth day the first fly made its appearance, and by the morning of the seventh day the space between the muslin and the paper was swarming with them. He analyzed the events as follows: The ova are deposited in the latrines, and are conveyed in filth-carts to the trenches; the larval and pupal stages take place below the ground, and the developed fly makes its appearance between the covering of earth. He never succeeded in hatching flies in wet earth.

Most writers claim that flies do not travel far from the locality in which they are bred, and little is known as to just what distance they may cover. Professor Packard, according to Ernst,[13] gives the rate of speed of the common house fly as 5.35 meters per second, or a mile in 5 or 6 minutes, which is at the rate of 10 miles an hour. Packard thinks any of the flies can scent their food for several miles, and might fly 20 or 30 miles a day if aided by winds.

Our present accurate knowledge of the possible spread of diseases by flies is antedated, like many of our modern ideas, by the inferential observations of astute observers of past times. As early as 1498, in a work attributed to Bishop Knud,[24] is the statement that the plague may be foretold by frequent changes in the weather, much fog and rain, and the increased number of flies, and in 1577 Mercurialis noted that flies, after lighting upon the sick, visit other houses, depositing their contents upon bread and other articles of food.[26]

Sydenham[1] (1666) says: "From my own practice I know of only two observations by which we can prognosticate the healthiness of the autumn that is to follow; first, if fevers appear unnaturally early, the season that follows will be exceedingly favorable to the development of epidemics. I have remarked that, if swarms of insects, especially house flies, were abundant in the summer, the succeeding autumn was unhealthy. This I observed to be the case during the whole summer of the aforesaid year (1661), while in the summers of the two following years, which were very healthy, the insects were very few. Still, I must remark that at the approach of even so severe a disease as the plague, they were not observed to be very abundant. With these two exceptions I have observed that all prognostics are fallacious."

In 1853, "J. F."[24] referred to the increased number of flies in cholera times, and in 1873, Nicholas,[24] speaking of the cholera epidemic at Malta in 1849, states that he was then impressed by the possibility of flies transferring diseases, as they were present in great numbers, and had free access to dejections and food.

Marpmann[24] (1864) said that the natives of Friesland blame the spread of hog erysipelas to flies, and Francis,[24] in 1893, reported the case of a woman he saw in 1846 who developed cholera shortly after swallowing a fly, and who died from the disease. Joseph[24] believed that domestic flies may carry bacilli and deposit them on wounds, and that anthrax may result from infected flies being crushed on a wounded surface.

The inferential deductions of the better-informed writers of recent date should be admitted to the argument. Davaine (1868)[24] stated that the infinitesimal quantity of blood which suffices to transmit anthrax corresponds with the amount of fluid in the fly's proboscis. He claimed (1870) that the rôle flies play in the transmission of anthrax had long been known. Moore[7] (1893) suspected flies as being carriers of cholera, typhoid fever, tuberculosis, anthrax, and leprosy. Battersby[8] (1895) attributed an epidemic of typhoid fever to flies which were abundant, the water supply being beyond suspicion. Bachman[10] (1898) suspected the ability of flies to carry the eggs of parasites and deposit them on food. Joly[24] (1898) argued that if flies can carry pollen, why not bacterial matter. Veeder[18] (1898), noting a commode from which typhoid excreta had been recently emptied without cleansing, and placed next to a pitcher of milk, saw flies gather around both, endangering, in his opinion, not only that household, but the whole neighborhood.

Hervioux,[23] observing that in the epidemic of smallpox in Tamorna-Djedida the disease spread in the direction of the prevailing winds, placed the responsibility on flies. Abbott[25] and Rosenau[28] make flies responsible for much of the spread of typhoid fever, for they breed in and feed upon infected discharges, and convey the infection to the food supply, particularly milk. They may alight on the lips and other portions of the body.

Parke[27] notes the possibility of flies distributing anthrax, plague, cholera, typhoid fever, tuberculosis, trachoma, septicemia, erysipelas, recurrent fever, and leprosy, and adds that they may also transport the eggs of animal parasites and deposit them on food. Martin[33] observes that an increase in the number of flies is followed in about 1 week by a corresponding increase in diarrheic diseases, and in 3 to 4 weeks by an increase in typhoid fever. Nash[34] noted the unusual absence of summer diarrhea, and at the same time an absence of flies —the flies and enteric conditions appearing at the same time later in the summer.

Cobb[44] saw a box of dates exposed within 100 feet of 5 tuberculous patients spitting, and watched flies going from the sputum to the exposed fruit. Braun[50] lays the distribution of the oxyuris to flies.

There seems to be no restriction to the diet list of the fly. Common observation will show that anything organic serves as food. In Egypt they swarm around the sore eyes of the natives. In the hospitals they congregate around exposed wounds and dressings; in the field, on dead animals; in barns, on the sores and nares of sick animals, and wherever dejecta have been thrown or sputum expectorated there will flies alight and feast. The logical conclusion would be that whatever particles existed in these several localities small enough to be drawn into the stomach of the fly, passage of such would occur, and, if bacteria be present, make the host a receptacle and carrier of the same, to be disseminated later.

Any marked change in fly life impairs their vitality. In the open they undoubtedly live for a season; confined in bell-jars or cages at ordinary temperatures, a goodly number die within a week.[24 39 52] The health and longevity of flies also seem to be materially affected by the bacteria which they may ingest.

It has been noted that in plague laboratories dead flies are numerous, giving the suggestion that they might have succumbed to the effect of contained plague bacilli.[27] This has been proven by Davaine,[24] who fed 4 flies on anthrax blood, 3 of which died.

Nuttal[24] experimented with *Musca domestica* fed on animals dead from the plague at 14° C. All were alive at the end of 8 days. Another experiment found them all dead on the seventh day, whereas of the controls only 20 per cent. had died. In the third experiment all were dead on the eighth day, and 6 out of 14 died of the disease. At higher temperatures flies die more rapidly, mostly within 3 days. He states that the fact that infected flies can live for several days points to the probability of their playing an important part in the dissemination of the plague, as they have plenty of access to food into which they might fall and die, or on which, in again feeding, they would deposit their excreta laden with plague bacilli.

Lord[39] fed flies on tuberculous sputum, 10 to a field. Out of 30 flies, 26 died in 3 days, the remaining ones becoming inactive. Of the controls, 6 flies confined and fed on nontuberculous sputum were all found dead in 2 days. Of 6 others fed on water, sugar, and meat, and similarly confined, 2 died in 2 days; the remaining 4 were alive at the end of the week. A writer in the *Healthy Home*[52] found that confined flies fed on tuberculous sputum died within 2 to 3 days; controls, fed on clean milk, 8 to 10 days.

Experiments have been made to demonstrate how long bacilli would remain alive when dried on the external parts of the fly. From flies caught in an autopsy room at Hamburg during a cholera epidemic, after feeding on cholera bacilli, allowed t fly around a while and then recaptured, roll cultures were taken at intervals, giving positive results even after an hour and a half had elapsed,[4] and cultures were obtained from the tubes of the feet after 17 hours.[43]

How long organisms will remain alive in the gastrointestinal tract of the fly has been investigated by several experimenters. Although the number is not sufficient to be conclusive in each instance, still their results are entertaining.

Cholera bacilli were found in flies' dejections as early as 17 hours after feeding and as late as 4 days.[24] The bacilli of typhoid fever were found in the dejections as late as 23 days,[30] and tubercle bacilli as early as 18 hours.[39]

If the secretions of the gastrointestinal tract be not inhibitive, and bacilli remain long enough in the same at a proper temperature, there is a possibility of their increasing in number. This has been noted at least twice. Lord[29] found that the bacilli in fly specks had increased in size and showed evidences of branching. The bacilli in the field numbered 10, and in the dejections 150.

The strongest evidence, and the one least controverted, is the trinity of laboratory experimentation, the finding of pathogenic germs in the interior of the fly, the development of the same by cultures, and the production of disease conditions through inoculation. Numerous observers have taken the trouble to verify their suspicions.

Bollinger[2] proved the presence of anthrax bacilli in the stomachs of flies. Marpmann[24] squeezed fluid from the proboscides and ani of flies which had fed on erysipelas bacillus, and found cocci and bacilli. He also fed them with nutriment containing the bacillus prodigiosus and bacillus fetidus, with like results. Maddox[24] (1885) found live bacilli in their dejections.

Spillman[24] and Haushalter[24] found tubercle bacilli in the abdominal cavities of flies caught in a consumptive's room, also in specks scraped from the walls and windows of hospital wards for consumptives. They fed flies on tubercular sputum, and proved the presence of tubercle bacilli in the intestines of flies and in their excrements. Hofmann[3] made similar experiments and found bacilli in 4 out of 6 flies. Anthrax bacilli were found in flies' dejections by Celli[24] and Alessi.[24] Stiles[24] found the eggs of the ascaris in the larvæ and in the adult fly. Simmonds[4] (1892) examined flies present in an autopsy room at Hamburg and found bacilli in large numbers. Recognizing the source of danger, he ordered the bodies sewed up and the tables cleansed, after which no bacilli were found in the flies in the room.

Uffelmann[5] allowed a cholera-infected fly to drink out of a glass of sterile milk, and, after keeping the latter at 70° F. for 17 hours, found each drop to contain about 100 organisms. Yersin[26] (1894) also found living bacilli by microscopic examinations. Billings[11] found anthrax bacilli in the stomachs and intestines of flies collected from the body of an infected steer. Raimbert[24] made the first microscopical experiments concerning anthrax in flies in 1862. He kept flies in a bell-jar containing a vessel of anthrax blood diluted with water. After the flies had drank the fluid and soiled their bodies, he found bacilli in their proboscides in 2 hours, and later in the excrements.

Grassi[24] fed flies on water containing tænia eidium. The eggs came away unaltered in the flies' dejections. He also experimented with the oxyuris and trichocephalus, and caught some flies whose intestines were full of eggs. Similar results were obtained with the oidium and botrytis. Macrae,[24] in India, 1804, exposed boiled milk in different parts of a jail where cholera and flies prevailed. High walls separated the male from the female department. There were no cases of cholera on the female side, but the milk on the male side became infected with cholera germs. The milk in the cow-shed was also infected.

Lord[29] made sections of flies fed on tubercular sputum and found bacilli in the intestines, but there was no invasion of the other parts. On the examination of fly specks the bacilli appeared in the stools within at least 18 hours. Examination of many specks showed that the number of bacilli to a field increased from 3,000 to 5,000 bacilli. About 2,000 specks had been deposited by 30 flies in 3 days; thus from 6,000,000 to 10,000,000 tubercle bacilli had been transferred from the sputum to the inner side of the flies' cage during this period.

Raimbert's[24] investigations prove that house flies which live upon flesh and blood carry the poison on their feet, wings, and in their dejections. In 1862 Davaine[24] made observations on the spoiling of fruit and vegetables, which he traced to flies that carried the spores of penicillium and mucor, and infected the wounded places on apples, etc. Tizzoni[24] and Cattani[24] caught flies in cholera wards, secluded them for some hours, took cultures, and found cholera bacilli. Swatchenko[24] culturally found spirilla in flies' dejections after 2 hours. Uffelmann[5] experimented with 2 flies; the first yielded 10,500 colonies, and the second 25.

Hart[14] and Smith[14] cited an experiment by Burgess, who fed flies on bacillus prodigiosus and then allowed them to fly into a large room. After a few hours they were recaptured and made to walk over slices of sterilized potatoes, on which later were found vigorous growths. Smith[17] experimented with house flies walking over alternately sterile Petri dishes, and one with diphtheritic growths; thereby inoculating the sterile.

Veeder[18] made cultures of bacilli from fly tracks and excrements, the flies having fed on the dejections of typhoid and dysentery patients, thus showing the possibility of these diseases being spread by flies. Sangree[20] experimented with anthrax cultures on a wingless fly, allowing it to walk over first the culture plate and then over sterile agar, demonstrating the colonies which grew from the same. Ficker[30] isolated typhoid bacilli in bodies of flies caught in houses where people were ill with typhoid fever. He experimented to determine how long bacilli would live within the bodies of flies, and found the extreme limit to be 23 days after feeding. Hayward[38] fed flies on bacilli contained in tubercular sputum, cultures developing the same.

Chantemesse,[43] writing on the propagation of cholera from house to house, makes flies the most important factor. His experiments proved that one could obtain cultures of cholera after 17 hours from the feet of flies and from their intestinal contents. Similar experiments and results were obtained by Celli[24] and Alessi.[24] Davaine[24] inoculated guinea-pigs with proboscides, legs, and wings of flies removed directly from a jar. The animals died of anthrax. He also fed flies on anthrax blood for 24 hours, then after that sugar water for 1½ to 3 days. Four flies died of anthrax and three survived. He believes that flies are a most important means of spreading anthrax. Proboscides from flies which had sucked upon the erysipelatic leg of a horse were inoculated into healthy horses, and produced effects similar to inoculations made with the excretions themselves, and the proboscides contained bacteria similar to those seen in the wounds.[24]

Celli[24] and Alessi[24] proved, both by cultures and by inoculations, that flies' contents give off virulent anthrax bacilli. In their experiments on domestic flies they proved that the *Staphylococcus pyogenes aureus* was unaffected in its virulence by its passage through the fly's intestines. Celli (1888) fed flies with tubercle bacilli and inoculated the anterior chamber of the eye of a rabbitt, developing tuberculosis in that animal. Flügge[24] experimented with

the bacilli of anthrax, typhoid fever, spirilla, and *Staphylococcus pyogenes aureus* and found them virulent after passing through the intestines of the fly. Simmonds[4] proved that bacilli retained their virulence when adherent to flying insects for an hour and a half after drying.

Swatchenko[24] experimented on flies with pure cultures of cholera bacilli, and the bacilli were found in the excreta and bowels as late as 4 days later. When inoculated they were found to be as active as pure cultures. The same results were obtained when the flies were fed on choleraic dejections. Hoffmann[3] fed flies on tubercular sputum, and 24 hours after being fed bacilli appeared in the excreta of the flies, and 3 guinea-pigs inoculated with their intestines died with tuberculosis. The presence of plague bacilli in the intestines of flies has been demonstrated repeatedly. Yersin,[26] in 1894, noting the large number of flies where victims were being autopsied, crushed one fly and inoculated it into a guinea-pig, which died of the disease in 48 hours. Twelve hours after flies had been infected, Marpmann[24] (1897) inoculated their contents into mice. His experiments were not complete, in that although the mice died, not all of them died from the infection. Hayward[28] fed house flies on bacilli contained in tuberculous sputum and proved it by inoculation.

To test the virulence of bacilli in specks, Lord[29] protected glass jars from direct light. Guinea-pigs were inoculated with 100 specks each, scraped from the flies' eggs at intervals of 1, 8, 15, 28, and 55 days. The first inoculation was made subcutaneously and the other intraperitoneally. The animals were killed after 5 to 7 weeks. Tuberculosis was produced by the inoculated material in the first 3 animals, showing that virulent bacilli were present in the specks for at least 15 days. The pig inoculated with specks which had dried for only 1 day showed generalized tuberculosis. The pig inoculated with the specks which had dried for 15 days presented large, isolated, tuberculous lesions of the spleen and of two lymph glands, one in the gastrohepatic omentum, and the other in the anterior mediastinum. Tubercle bacilli were demonstrated in these lesions.

An interesting condition which occasionally occurs is due to the ingestion of fly larvæ by human beings. Certain species of the larvæ of flies are capable of reproducing larvæ,[9a] which accounts for the gastroenteric condition with which they are associated. Bachmann[10] found larvæ of the common house fly in the vomitus of a hard drinker, and the same were found by Cohen[12] in the dejections of a nursing infant. Another writer[9] cites a case in which fly larvæ in large masses were passed in the stools, and a case is cited by Cattle[30a] in which large quantities of dipterous larvæ were passed per anum.

Stiles[24] found the eggs of the ascaris in the larvæ of flies.

Disease conditions and associated states accurately observed must be considered scientifically as trustworthy experiments as those done in laboratories. A change in the water supply from foul to pure, with the incident reduction in enteric conditions, demonstrated as positively the source of typhoid fever as any inoculation of pigs.

Not until the Spanish-American War, in 1898, did we realize the importance of the fly question in the dissemination of typhoid germs. The Civil War gave us modern hospital construction, so this latter, the Spanish-American, may result in proper relegation of aërial diffusion of disease, and the placing of diffusion by flies more prominently. Sanitation in the army at this time was not as carefully prearranged as it should have been, and as it was at the time of Moses.[9] The fly factor was not unknown, and yet no provision was made in the sanitary regulations to prevent the dissemination of the ever-present typhoid fever by these agents. Not only were the contents of the latrines exposed, but the men wandered through the woods defecating indiscriminately.

Quoting from Reed, Vaughan, and Shakespeare's Report on the Spread of Typhoid Fever in the United States Military Camps during the Spanish-American War of 1898:[48] "Typhoid fever progressed even in those who did not drink the suspected water. Notwithstanding the purity of the water supply, and contrary to the opinion generally accepted by the medical profession, we find typhoid fever, having been imported into various company organizations, now steadily advanced. The disease is attributed to the fouling of the ground, inevitable in camps, the lack of sufficient conservancy establishments, and the contamination of food through the agencies of dust and flies. . . Flies swarmed over fecal matter and then visited and fed upon the food prepared for the soldiers in the mess tents. In some instances, where lime had recently been sprinkled over the contents of the pits, flies with their feet whitened with the lime were seen walking over the food."

Not until a spade and an armed soldier were placed at each latrine did the fly menace cease and typhoid fever diminish. As each man defecated, he was compelled, with his spade, to dig up enough earth to cover his excrement, the sentinel seeing that such order was carried out. No sadder, more humiliating, yet successful experiment has ever been noted.

Buchanan[9] relates an attack of cholera in the Burdwan jail, where the water supply was above suspicion, and the same for all the inmates, who were divided into groups, separated by a high wall. One group had their victuals cooked separately and were fed in separate places. The ones fed close to the latrines, where choleraic discharges were thrown, became infected with cholera, while the other group escaped. It was fly year, and flies were seen to come and go between the food of the inmates and the discharges in the compounds.

In 1850 the ship *Superb* had cholera on board. She was at sea for six months. On putting to sea flies were in great force, but after a time disappeared, and with them the epidemic. Going into Malta the flies again appeared from the shore and cholera increased. Again putting off to sea, the flies disappeared, with the coincident subsidence of the disease.[6]

Alice Hamilton[32] sums up the result of her study into the part played by the common house fly in the recent epidemic of typhoid fever in Chicago, which could not be explained wholly by the water supply nor on the grounds of poverty and ignorance of the inhabitants, as the section infected did not differ in these respects with several other sections. The streets in which the sanitary arrangements were worst had the larger number of cases. Flies caught in undrained privies, fences, walls of the houses, and rooms of typhoid fever patients, showed typhoid bacilli in 5 out of 18 cases. Further, she states that when the dejections of a typhoid victim are left uncovered in privies or yards, flies may be an important agent in the dissemination of the disease.

Hewlett[45] noted an epidemic of flies coincident with an epidemic of enteric diseases among children,

in which the diseases affected alike all classes, under conditions sanitary and unsanitary.

How diseases are transmitted, and the most probable source in each circumstance, have naturally been the cause of much argument. As the science of medicine has become more exact, and as the methods of experimentation allow of more logical deductions, so have some of the opinions once thought worthy lost in favor. Naturally, several channels exist, some always dangerous, others occasionally so.

The possibilities of aërial dissemination of pathogenic germs, once holding the confidence of the profession, has been seriously attacked. How important flies may be in the dissemination of diseases will largely depend upon other existing conditions. The observations referred to herein conclusively prove the possibility of the spread of any type of infectious disease by this insect. It has been aphoristically stated that "the three great means for the transmission of typhoid fever are fingers, food, and flies,"[36] and the authors hold the last to be the most important. If this be true of typhoid fever, why not of any other microbic disease?

The part of the fly most active for harm is undoubtedly the portion which most carefully protects the contained microbe from sunlight and desiccation. From the experiments recited the relative danger is as follows: the dejecta, the proboscis, the crushed or ingested insect, and the outside parts.

Scientifically speaking, the number of flies in a community is in direct proportion to the carelessness of its sanitation. The housekeeper will spend a day rummaging over a bed for a bedbug, and give little notice to a kitchen full of flies. "The presence of flies in a house is a reproach, falling away from the high hygienic standard, for the fly is a pestilential fellow."[3a] Fly epidemics are generally local ones spreading slowly from the source of first infection. Winds, by carrying the flies, allow of spread in their direction. As a working hypothesis, which is both logical and reasonable, one can explain the sporadic occurrence of epidemic diseases, such as remote cases of cholera, which are not native and existing in quarantine. Further, it has been repeatedly asserted that in the zone immediately surrounding a smallpox hospital new cases are more frequent than at a distance. There are two ways to explain this condition—the wafting out of the building of infected particles, or the carriage by flies. The latter seems more probable, for outward drafts are never vigorous, and hardly sufficient to carry a distance.

Every privy, every open window, every dead animal in the street, expectorations of people suffering or incompletely recovered from any infectious disease, the nares of scarlatinal patients suffering from catarrh or acquired colds; in fact, all conditions where pathogenic bacteria or intestinal parasites may openly exist, make possible, and even probable, the spread of disease by flies. This, being known, should be acted upon. There are few Boards of Health as intelligent and far-sighted as that of Philadelphia, which has taken vigorous measures to protect the public against infection of food by flies. Inspectors are directed to visit all milk houses, butcher shops grocery and candy stores, and instruct the owners to place a covering over all articles. The order reads:[47] "The chiefs of divisions of nuisances, milk and meat, and cattle inspectors are hereby instructed to visit all retail dealers exposing for sale in front of their properties meats, fish, vegetables, fruit, candies, and cake and instruct the proprietors that a covering of some suitable material must be provided to protect the goods so exposed from flies and insects generally."

When mosquitos were discovered to have a part in the dissemination of malaria and yellow fever, it was thought that a prevention of their breeding was too great a proposition, yet it has been satisfactorily accomplished, so that now one case of yellow fever in all Cuba will create more comment in the daily papers than at one time an epidemic in Havana. Certainly when the profession and the laity become alive to the dangers incident to the presence of flies, and recognize in them a receptacle and a carrier, then will the problem be attacked and solved.

Attached to all stables there should be built a pit of sufficient size, closed tightly with the exception of a ventilating window properly screened, and so constructed that little direct light may enter. Manure, as soon as dropped from the animal, should be pushed into this pit, and chloride of lime or crude oil frequently scattered over its contents. All organic filth, such as human manure, if conditions do not allow of a sewerage system, should be covered immediately by sufficient earth. All offal and organic débris, in which flies can lay their eggs and propagate, should be disposed of, secluded, or screened. Hospitals, particularly where contagious diseases exist, and rooms containing the same, should have all windows and doors carefully screened, and every effort be made to rid the interior of such flies as may enter. All food, particularly milk and such articles as are eaten uncooked, should receive full attention and protection.

280 MONTGOMERY STREET

PHYSIOLOGICAL ACTION OF MASSAGE.

BY GUSTAV NORSTRÖM, M.D (STOCKHOLM),

NEW YORK.

WHEN by careful observation the efficacy of massage had been demonstrated in several affections and morbid states which had nothing in common, apparently, at least, it became desirable to explain its action. Empiricism paved the way, which later on was widened by reasoning and experimenting. As late as the last century it had been observed that friction accelerates the venous circulation and diminishes existing stagnation.

The affections in which massage had yielded the best results, and in which it had been most used and most recommended, was in cases where the normal relations of the tissues or their elements were altered. In sprains we find vascular ruptures and sanguineous effusions. The presence of hemorrhages, or extravasated leucocytes, in a region, gives rise to disturbances if their absorption requires a long time. In hyperplastic arthritis, hydrarthrosis, inflammation of the tendinous sheaths, we have to deal with new solid or liquid products, and we can only expect an entire functional restitution, a real cure, if we cause them to disappear. From this point of view massage is really useful.

The first condition which is necessary to obtain a clear idea of the physiological action of massage is to become familiar with the laws of nutrition of the tissues, of which absorption is one of the main factors.

The living cell is an organic center, which undergoes development, lives, and then dies.

Certain liquids are as indispensable to organic elements as salt water is to fish, fresh water to mushrooms, vinegar to mycoderma aceti. They contain water, albumen, and salts. No doubt, their composition varies in the different tissues, but we do not know the character of these variations. It is from these liquids that the cells derive their nutritive material. These liquids are known under the generic name of "parenchymatous juice." This latter is absorbed by the tissues. To this imbibed liquid the tissues owe their essential properties. Let us compare a piece of tendon, of cartilage, or of connective tissue, in the normal state, with a fragment that by desiccation has lost its imbibed water; the volume, color, and consistency, in a word, all that may be rendered manifest by the naked eye, has been altered.

One might, to a certain extent, compare the liquids contained in the imperceptible lacunæ to the crystallization water of certain inorganic bodies, with this reserve, however, that the proportions of the former are not fixed and determined like those of the latter. The part which such liquids play in our economy is easily perceived when we reflect that most tissues contain more than 75 per cent. of water. The parenchymatous juice is contained in spaces of microscopic size. These spaces, called lymphatic spaces, are of many shapes, such as lacunæ, channels, sacs, etc. The fluid is found in nearly all parts of the body, but above all it is in the connective tissue, which may be considered the true reservoir of parenchymatous juice.

Having obtained this conception of the parenchymatous juice and the part it plays, it is easy to deduce from it its importance for the economy. An animal cannot indefinitely live in a small room, hermetically sealed up; when the exhaled air reaches too large a quantity life ceases. A periodic renewal of the air is necessary; that is to say, an addition of respirable elements and an evacuation of expired air. The phenomena in the interior parts of the tissues are exactly similar.

The terminus of the nutritive channels is the capillary plexus; the channels of evacuation are the veins, and especially the lymphatics. The difference in pressure in the interior of the centripetal and centrifugal vessels play such an important part in the flow of the liquids that it cannot be altered without impeding the current. If the venous tension is increased beyond a certain coefficient, the lymphatics suffice no longer to accomplish their task, and the region becomes edematous. The same phenomenon is produced if these lymphatics themselves are altered and have become partly impermeable. When it is desirable to obtain very quickly edema of a limb by venous compression one ought to pass a ligature around a big lymphatic trunk, as has been shown by Cohnheim. Massage, which is, as we have already said, a powerful adjuvant to absorption, acts on the venous and especially on the absorbing system. It accelerates the current of the liquids in all directions, and by diminishing the tension in one part, facilitates, by the production of a sort of a vacuum (suction force), the circulation in the next succeeding one. This theory will allow us to understand most phenomena and will justify the manœuvers resorted to, though they may seem strange and their application present difficulties. For instance, in articular affections, massage acts on absorbing vessels, but we know scarcely anything about the lymphatics of the joints. What is their origin? How do they behave as regards the synovial fluids? Do they end in cul-de-sacs, without epithelium, as was generally believed a few years ago, or do they open into the cavity by stomata?

When Mosengeil set to work to study the phys-

iological action of massage, he stood amazed when confronted with all these problems. As histology had taught nothing, experiment alone remained.

Mosengeil's experiments will forever remain classic, because they have thrown a new light upon massage and the origin of articular lymphatics. Besides theoretical difficulties, there are technical ones. If you desire to study the influence of massage on the progress of arthritis, for instance, it is quite a simple matter; take two animals and introduce into two similar joints a colored liquid, the progression of which is possible to observe with the naked eye and with the microscope. But the selection of such a liquid is not an easy one. Vermilion grains are too big and angular, and when filtered the chemical products are colorless. Mosengeil, after considerable meditation, chose India ink. This must be of such fine and good quality that its dilution is uniform throughout, without containing any small particles and without producing the least sediment. As soon as the solution had been prepared, a sufficient quantity was injected into the two femorotibial articulations of a rabbit; one of them was massaged, the other one not. The result of Mosengeil's experiments were always the same. On the massaged side the diffusion of the liquid took place rapidly; it was propelled into the lymphatic vessels and plasma spaces of the thigh, the direction being from the periphery to the center. On examination of the unmassaged joint a most striking contrast was found. The joint remained distended. In only one case was there found a lymphatic ganglion of the thigh impregnated with the fluid. But one ought not to conclude from this that the afferent vessels had carried the liquid from the synovial cavity.

Repeated abundant injections had caused a tumefaction of the knee. This pressure, due to the increase of the liquid, had not, however, as massage had done, driven the colored substance into the absorbing vessels. It had infiltrated places where it found the least resistance, namely, the neighboring connective tissue and that which separates the muscles of the leg. It is possible that the movements and the action of the force of gravity favored this evolution; it is also possible that traces of the India ink found in a ganglion of the thigh, were brought there by lymphatics of the infiltrated interstices. No ambiguity is possible in the interpretation of these facts. Massage had driven the material into the centripetal vessels, it had stimulated its absorption to such an extent that there was no comparison between the massaged side and the other. Yet the animal was not secured; it was allowed to run and jump about; the muscular contractions were as active in one as in the other limb. They favored the progress of the liquids in the right just as much as in the left lower extremity. Another argument in favor of our hypothesis is this, namely, that the operative procedure is of a serious importance. In some cases where massage was performed by unskilful hands there was no liquid in the lymphatic ducts, but simply a diffusion into the cellular tissue.

From what precedes, we may conclude that massage is an energetic agent: it sometimes brings about complete resolution, but always favors the absorption of the preformed products, which it directs into the lymphatic centripetal vessels. Procedures which at one time may have seemed purely empirical, are really rational.

Mosengeil was the first one, I believe, to undertake researches with a definite purpose in view, namely, to no longer study the physiology of one or other tissue, and the manner in which it reacts after various excitations, but to see in what massage really consisted, to discover the difference between absorption and diffusion of a colored substance, injected into a limb which had been massaged, and in one which had not.

This difference is as clear as it can be. In the first case we have had processes comparable to pathological ones, the foreign material has been absorbed and transported. It is easy to understand what would have happened if, instead of India ink, a poisonous substance had been introduced. In the second case it is useless to suppose the interference on the part of any vital power, the liquid permeated the connective tissue by imbibition in the same way as if it had been infiltrated in any other tissue. These facts do do not stand isolated; experiments have yielded results. It was easy to foresee that others would endeavor to complete them.

Sturm and Salis have obtained exactly the same results as Mosengeil. Reibmayer and Haffinger have extended their experiments on articular synovials to the peritoneum. They injected water into the peritoneal cavity of several rabbits; one of them was massaged (*pétrissage* of the abdomen) for ten minutes, and another one was left alone. An hour afterward both were killed. In the case of two other rabbits massage was given for two consecutive hours and then they were killed. During the first hour there was less reabsorption in the massaged rabbit than in the other. The modifications, in the shape of abdominal pressure and aspiration, resulting from the maneuvers performed during the first hour, had altered the conditions during second. Here are the results as Kleen has recapitulated them:

	Proportion per cent. of the weight of the water compared to the weight of the reabsorbed body	
	Without massage	With massage
1st hour	4.57	9.09
2d hour	5.83	1.29
Total for 2 hours	10.40	10.38

Massage modifies the absorption in the interstices of the tissues, as well as in serous surfaces; several factors contribute to it. We have sufficiently insisted upon the prominent part which the lymphatics play. The sanguineous current does not remain inactive either, the pressure exerted on the veins hastens their depletion and diminishes stagnation, if there is any. It has been said that something similar to what happens in the suction pump is produced. I would rather compare it to the classical aspirators used by physicists. The more rapid the current is, the more energy is developed by aspiration. But is there any advantage in massaging? The arterial circulation is centrifugal, and our frictions are directly opposed to it. No doubt about this; but the arterial trunks are deeply seated, their walls have a contractility of their own, so that, fortunately, these slight and temporary obstacles are easily overcome. The *vis a tergo* remains exactly the same in the capillary system, whether one massages or not. The propulsive force remaining constant and the venous tension diminishing, the resultant is an increase of the arterial circulation in a given region and a diminution of the congestions. We may consider the isolated cell as a complete apparatus, endowed with a marvelous power of adaptation, the physiological functions of which are greatly influenced by our treatment. If the movements of the fluids in the living tissues are slow, the action of mas-

sage will be most potent and sure. The circulation becomes easier, the absorption is improved, the chances of exudation, transformation, and organization of the exudate diminish. It is also possible that when an exudate already exists, it may entirely disappear through our manipulations. But if we have to deal with a plastic exudate, an additional measure, not yet spoken of, is necessary to cause its disappearance.

We have placed before us the most simple hypothesis. We ought not to break a fiber, nor reduce a mass to fragments. Practitioners of massage must modify their methods to suit the cases; if they have to deal with tangible and definite lesions, they have not only to pass the ball of the thumb or the palm of the hand lightly over the surface of the body (*effleurage*), but they have to use friction and *pétrissage*; and this simply because in these cases absorption cannot be accomplished without preliminary fragmentation. The acceleration of the lymphatic current is not sufficient to cause an old, organized exudate to disappear. The latter must be brought to a very fine state of division, very much like the diluted India ink of which we have just spoken. Its particles must be small enough to be received by the mouths of absorbing ducts. Energetic massage produces all this. There is besides another advantage to be derived from this kind of massage: that of destroying the capillary vessels which nourish the organized exudate. The acceleration of the blood current is further increased by the intervention of the nervous system. Sometimes also by that of the muscular elements.

Very often when we have to deal with muscular lesions we have recourse to the manipulation called *tapotement*. The infliction of successive slight traumatisms produced by this maneuver is the best means of producing excitation. Schiff, Kühne, Kölliker, have shown that the mechanical irritation is sufficient to provoke contraction of the muscular fibers quite independent of the nervous system. This is quite an excellent means of accelerating the circulation.

Zabludowski ("Die Anwendung der Massage für die Chirurgie und ihre Grundlagen") has proven by an ingenious experiment that massage can cause rapid disappearance of all fatigue. A person at rest supported a weight, with the arm flexed, until the arm was fatigued; effleurage was performed for five minutes, and at the end of that time this same person was able to perform more muscular labor than before. On the other hand, if no effleurage was resorted to, he was obliged to wait at least a quarter of an hour before being able to resume work. Besides, the contractions produced reflexly after massage are more powerful than before. Zabludowski also observed that massage had no influence on the reflex excitability of the spinal marrow, but as it increases the power of the muscles, we render their contractions more powerful.

E. Kleen ("Handbok i Massage") tells us that a friend of his, a leader of an orchestra, has his arm massaged by effleurage every time he conducts his musicians for considerable time; he thus experiences far less fatigue than if he did not have recourse to this measure.

This action on fatigue may also be explained by the assumption that absorption is increased. The sensation of fatigue occurs in consequence of the oxydation of the tissues and of the accumulation of phosphates, carbonic acid gas and lactic acid. If their disappearance is hastened, fatigue ceases sooner than it would by rest alone.

Physiology explains the action of massage on neuralgia, as well as that of pressure, tapotement, and trepidations, along the course of the nerves. These manipulations I often had recourse to, especially in neuralgias of the forehead or the face, where the nerve is seated sufficiently superficial to be accessible to them. Slight pressure on the nerve provokes its excitement and intensifies the pain, whereas very firm and strong pressure is followed at first by numbness and then by more or less anesthesia. The same thing takes place with the motor nerves, as Tigerstedt ("Studien über mechanische Nervenreizung," Helsingfors, 1880) has shown that their excitability is augmented by a very slight pressure, and diminished or entirely suppressed by a strong one.

122 East Thirty-fourth Street

PROPRIETARY MEDICINES.*

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

I wish to tell you this afternoon a few solid truths regarding proprietary medicines, to which, like all truths of science or religion, there may be exceptions. I had believed until one year ago in the law of gravitation, and believe in it to-day; yet, according to the latest scientific investigations, this law may be questioned.

I wrote editorially in the *New York Medical Journal* some two years ago on the subject of "Proprietary Medicines," and have nothing to add, nor do I know whether I can now say as well what I wish to say as I did then. However, I wish to emphasize a few fundamental ideas in a simple way.

What is the reason for the existence of proprietary medicines, and why are they sold? On any rational ground this is difficult to explain, but it is certainly true that many people, despite reasoning, love mystery and like to be deceived. I want to emphasize the fact that nearly all proprietary medicines are mysterious and some are humbugs.

Another peculiar fact is that many people think of a disease as a personality, as having an entity which may be and is properly combated by a certain remedy, simple or combined. This means to them that given a disease or even the name thereof, it must be immediately attacked by its antidote under the form of some proprietary preparation. No matter that they know nothing of the maker of the preparation, of his character, or his capability; the medicine is good for all equally and must be beneficial if taken as advised on the bottle's label. Many are killed by drugs or combinations of drugs about which they know nothing at all. They know nothing of the patient or his history, antecedent or present, and conclude that because the medicine appears to have helped some one else it will be useful in the case at hand. Such a person might be considered quite conscientious, but he has very little brains or else does not use what he has.

Now, with regard to all this literature and those bottles here before me, it is evident that the number of proprietary medicines is ever increasing, and that we are literally swamped with them. Many of these medicines are not only good to look at, but sweet to the taste. All these circulars, advertisements, and so-called scientific reports, whether written by real or unreal medical brethren, are not worth a whiff. The greatest sinners, however, are not the persons who interview you in the office

*Delivered on November 28, 1906, before the class at University-Bellevue Medical College.

and leave these samples around, but the manufacturer and the men of authority in the business world, men of high position who have so far disregarded their brains and consciences as to place their signatures at the bottom of circulars, lauding that about which they actually know nothing. Take the members of our faculty; do you find their names on such wares? Such men would never think of sanctioning the claims of those who send out these circulars and drugs. Because a man is acquainted with all the crimes in the world it is not necessary that he should indulge in them. I am sick and tired of so many circulars, advertisements, and so-called scientific reports.

Suppose a man who represents a house that I know about and which has an honorable record, and I know that I can take his word and rely upon it as well as upon his bond, now if he tells me that a certain drug, or combination of drugs, is good, I can rely upon it. We must rely upon something. In such a case I listen to the man because I want to learn what I can from him. There are some firms that have been working for years and years, getting all the knowledge they can concerning certain drugs or combination of drugs. If we may rely upon the character of these firms, and if the printed formula seems unobjectionable or desirable for any given case, we may, in my judgment, under certain circumstances, properly prescribe their drugs. There are times when to formulate a mixture rapidly, one that is suitable to a particular patient, is very difficult to accomplish in a satisfactory manner, and if we know or firmly believe that a proprietary combination will do as well as anything that we can write for immediately, on account of the great care in its preparation and its precise and accurate combination, we are justified in selecting it.

Is it advisable to keep certain drugs and mixtures at drug stores: does it look too much like commercialism? It is useful to have on hand at some reliable druggist's a mixture formulated by the physician himself to meet best in treatment certain aspects of disease. To do so saves time and thought and solves more than one perplexity in actual practice. This plan is resorted to by some honorable specialists, and even a few general practitioners, and has its favorable and also unfavorable side. You can go to a certain drug store in this city and ask for a certain physician's prescription for rheumatism, for instance, but you will be told that you cannot have it unless the doctor gives his consent.

There is another point. There are certain firms that put up certain preparations better than other firms. There are methods of preparation, probably, or a certain special skill or care as to the nature, use, and compounding of agents of materia medica, which render a particular remedy of one firm more active and powerful than a similar preparation sold by other firms. I advise the patient to go to those firms which have acquired knowledge which justifies me in sending them there.

How can we stop quackery? How can we prevent drunkenness? We may say by stopping the manufacture of alcohol. That is radical, but not practical. We can stop the sale of proprietary medicines in the first place by never sending the patient to any house or drug store unless we feel from all evidence that is obtainable that it is reliable. Secondly, we need never prescribe any particular mixture or pill unless on reliable evidence that the pill or mixture contains precisely what we called for; which brings one back to the question of reliability of the firm.

In most proprietary medicines we find document after document telling what is in the mixture, but the formula is omitted, and we know nothing about the firm manufacturing them. There are some men perfectly correct, proper, high-toned men, who prescribe proprietary medicines, believing that the combinations represent what is reasonably true, but one must know all about them before it is safe to prescribe them. As with the physician, so with the druggist, the whole matter hinges on the words honesty, a square deal, character.

Here is a bottle with the written formula which was given me by a former general practitioner, an honorable and reliable man, who lived most of his life practising medicine in a town where the work was not easy. As the result of his experience and life work he concluded that this formula, as on the bottle, was a desirable one. He has had the medicine made up and will vouch for it. I believe in him, and therefore I believe in the formula. I consider it a rational one, and I believe it represents the truth, and that it will be useful. The dose is here given, and the label states that it is to be given for neutralizing the substances that have developed from gastrointestinal fermentation. Of course there may be some patients on whom this will do no good, as certain drugs may at times fail us. There are no two patients precisely alike. I have seen many cases of pneumonia, yet I have never seen two that were alike; and the same may be said of scarlet fever, measles, and typhoid fever, as well as many other diseases. At the same time it is almost impossible to explain these things to ignoramuses. They cannot comprehend them because they have not had the training.

Yesterday there came into my office one of the best men that I ever knew, who lost his arm in the War of the Rebellion. Some one had told him that he had a leaky heart and this left him in a condition of mental worry, so that he thought that he might die at any moment. It took me one hour to disabuse him of this nonsense. It all comes back to the question of reliability. You select your lawyer and your dentist because you have confidence in him, and you should select your doctor in the same way, and then say, "I am in your hands: tell me what to do and I will do it. It is because of your knowledge that I have come to you." The doctor then sends him to some reliable place where he can get good and reliable drugs, and the patient follows the physician's directions.

I hope I have driven home certain things which no textbook in the English language will tell you. The papers have been filled with this kind of material and I have given you a résumé of what has appeared in them.

AN UNUSUAL NIDUS FOR GONOCOCCIC INFECTION.

By EDGAR G BALLENGER, M.D.,

ATLANTA, GA.

LECTURER ON GENITOURINARY DISEASES, ATLANTA SCHOOL OF MEDICINE.

From a review of the literature relative to the subject, I have not been able to find record of a condition similar to the one described in the following report, which shows that we should be on the lookout for gonococcic foci in other locations than in the urethral mucous membrane and the connecting glands, and is also of interest on account of the method used in anesthetizing the penis.

The patient, Mr. P., was a traveling salesman, nineteen years of age. General health had been

excellent, but he suffered with many nocturnal emissions, often two or three during the night. This condition had obtained since puberty, as had also a severe facial acne. Gonorrhea was contracted one year ago, and lasted eight weeks, but he thought this had been completely cured.

The foreskin was very long and adherent to the glans penis on each side, the middorsal portion having ruptured and left about half the circumference of the glans free and normal except at each end of the adhesions. In these two corners were raw surfaces, from which the prepuce had been torn during sexual intercourse five days before. A mucopurulent secretion was oozing from these reddened and inflamed points. There was also a urethral discharge which contained many intracellular diplococci, and the patient had the usual symptoms of gonorrhea.

An organic silver salt was used as an urethral injection; balsams, in small doses, were given internally, and stearate of zinc was dusted upon the lesions on the gland after gently cleansing each time.

All the symptoms rapidly improved until there was no discharge and only a few urethral threads in the urine. The erosions healed except in a small pocket on each side, just behind the corona and under the edge of the adherent portion of the prepuce. These exuded a tiny drop of pus, but appeared so nearly well that I gave them no concern when the patient left the city two weeks from the beginning of the treatment and took a twenty-mile drive into the country. This started a profuse purulent secretion from the small pockets, and the foreskin and glans surrounding them again became red and inflamed. Two days later urethral discharge followed with all the symptoms of gonorrhea. The treatment as first given was reestablished and continued for three weeks, when the urethral shreds, as well as the discharge, entirely cleared up. There was still, however, a slight redness in the little pockets under the prepuce which were now not larger than small peas.

In describing to me the manner in which the first relapse occurred, the patient did not explain the details about the discharge having started in the abovementioned pockets and two days later involving the urethra until the appearance of the second relapse, while he was here in the city. He came for treatment the first day the inflammation began, and at this time there was no urethral discharge, but it appeared the next day. The similarity and course of these two relapses convinced both the patient and myself that these pockets were the foci of infection. Smears were taken from them with a platinum loop and stained for gonococci, which were found very abundant from both sides; they were intracellular, and would not stain by Gram's method.

The same treatment was again advised, and the urethral discharge and threads, as well as the secretion from under the foreskin, soon disappeared, only a little redness remaining in the pockets. Another smear was taken from their interior, and, although there was barely enough secretion to examine, it showed large numbers of intracellular diplococci. No cultures were taken, but the typical attacks of gonorrheal urethritis that spread from these little cavities clearly showed them to be the seat of the infection.

After breaking the adhesions and cauterizing these patches with nitric acid, no further recurrence has been observed, and three months have passed since the urethral discharge and shreds cleared up.

Anesthesia was obtained by injecting twenty minims of a one per cent. solution of cocaine into the region of the dorsal nerve of the penis close back at the penopubic angle. This gave immediate and complete anesthesia, so that no pain was felt while freeing the prepuce from the glans or in the subsequent cauterization.

In November, 1905, I called attention to this method of procuring anesthesia of the penis,* and have used it on many occasions with most satisfactory results, and I believe it worthy of more attention than it has received. In circumcision, cauterizing chancroids, replacing the swollen glans penis in paraphimosis, or in any condition where anesthesia of the penis is desired, I know of no method in which the result may be more promptly and expeditiously obtained. The nerve can be easily found with the artery and vein by picking up the tissues in the middorsal line of the penis back near the symphysis pubis, and rolling them between the fingers. The small hard cord is the nerve. The cocaine need not necessarily be injected into it, but if the different layers of connective tissue immediately around the nerve and its branches be infiltrated the entire penis anterior to this point will be quickly anesthetized with a very small quantity of cocaine.

So far I have not amputated a penis, using this method, but see no reason why the operation could not be done under anesthesia obtained as above described, where there is no necessity for making the incision too near the root of the penis. If occasion demands, a few drops of adrenalin chloride solution may be added to the cocaine to prolong its effect.

An interesting feature of this patient's course, after breaking the adhesions, was the promptness with which the nocturnal emissions changed from one to three nearly every night to only one in two or three weeks. There was also a marked improvement in his facial acne, which from the history seems to have been due to sexual irritation

1014 Century Building.

*Strictures of the Urethra: Their Pathology and Treatment; *Medical News*, November 11, 1905

TEN YEARS A NASAL PATIENT.

By F. K. MacMURROUGH, M.D.,

JERSEY CITY, N. J.

I WRITE this without notes and without references. Ten years ago, in consequence of catarrhal and obstructive symptoms in nose and throat, I sought relief at the hands of a noted specialist. At the first examination he expressed professional delight at seeing the conditions that obtained in the nose. "It is a remarkable case," said he. "Well," he added, "we will clean it out for you." At that sitting he snared out the left middle turbinate, which was encysted. He could get only half of it, and I had to return in thirty-six hours with symptoms of sepsis and pain, when he removed the other half, already detached, and also removed eleven polyps of various sizes from large to small. At the next operation, a month later, he took off with saw a large exostosis from the left side of the septum, and performed at the same sitting a partial septum operation, *i.e.* moving the septum over toward the opposite side. I will state here that I am of a highly hopeful, optimistic temperament when I think everything is as it should be, or that such a condition of things is attainable, or maintainable. I will state also that I always had a ready voice for vocal, conversational, or even elocutionary or oratorical purposes, and that this readiness had been lost or impaired, and that I was in consequence mentally and physically depressed. Being of the blood of the Gael, I suppose it went hard with me to be

vocally incapacitated. Now, this optimism of mine led me to believe that each operation would be the last and that I should obtain relief and a restoration of my "lost voice."

The right side of the nose was always accounted to me to be the clear side, the good side, and I thought the work would be limited to the left side. Well, the left side cleared up marvellously, but *pari passu* the right side became occluded. I first had part of the right middle turbinate removed, then the posterior tip of the right inferior turbinate, then had the pharynx cauterized with electric cautery for possible speaker's sore throat, for I had become a speaker (a political campaigner). These measures brought some relief. It is true that in many nasal operations you are "six months sick before you get well." So I was always either recovering from an operation or getting ready for a new one. I then had more of the right middle turbinate removed and had the right side of the septum sawed and planed off, and at this time had one large polyp removed from the right nasal fossa.

I still suffered with catarrhal and obstructive symptoms and a "ruined voice." I was determined to persevere. I said to the doctor (God bless him for his patient, painstaking skill and never-failing charm, kindness, and courtesy), I said: "Doctor, I am looking for a perfect result, or at least an approximately perfect result." "Very well," he replied, "we will keep on until we reach it." Persons had said to me: "You can never get cured of catarrh." Doctors had said: "Once a nose patient, always a nose patient." Well, I was determined to be always a nose patient until I either enjoyed relief in life or relief in the opposite way. I always had abiding faith in the Doctor's skill and ultimate success. About five years ago the operation for submucous resection of the nasal septum was described. It was, of course, like all new things a *terra incognita*. It was discussed and tried timidly, reluctantly, here and there. After a year or two, or three, it became better known; results following it seemed to be satisfactory. I called the doctor's attention to the condition of the right side of my septum, high up, *i.e.* the deflection of the perpendicular plate of the ethmoid to the right side. He said he would do a submucous operation on it, and he did so. He removed considerable cartilage and bone. This wound healed quicker than any of the others. He said to leave it alone for a year and we would see what relief I had obtained. During that year I was better than I had been for years before as to vocal power and expression, but I was still crippled, still a sufferer. In just a year's time I called up the doctor on the telephone and told him I had determined on another submucous operation. "All right," he said, "come along," making an appointment. Well, the second submucous was done, this time taking out a high, bony ridge reaching nearly to the roof of the nose, and since then I have experienced the desired relief. The catarrhal condition has vanished, the voice has its old-time compass and resonance, and the mental picture is brightened again. Optimism is the word. There were twelve operations in all, covering a period of ten years. So, "those who persevere to the end shall be saved."

100 Lafayette Street

Dupuytren's Contraction Cured by Medical Means.—Gustavo Ferrari brings forward a case of contraction of the palmar fascia in an elderly man which had existed for some time. An operation had been refused by the patient and he had recourse to applications of cold running water to the entire hand, with the result of a gradual cure of the condition and a return to the normal function. There has been considerable difference of opinion among medical men as to the origin of this contraction and its treatment. Dupuytren considered it a local malady of professional nature, seated locally in the palmar aponeurosis, unilateral, belonging exclusively to old persons, and of the nature of a dystrophy. By others it has been regarded as a malady found in the lower extremities, in young persons, having its origin in a general disease; according to some of metabolism, to others of the nervous system, with lesions in the cerebrospinal axis. The author believes that we can reconcile these differing views by considering that there are several forms of the disease, some are professional or traumatic, others are dependent on alterations of metabolism, and still others are due to an alteration of the cerebrospinal axis. These latter cases have also present atrophy of the muscles of the hand and forearm, and are thus easily to be distinguished from the purely local forms. He considers it demonstrated that the disease may be cured by medical means without having recourse to surgical interference.—*La Riforma Medica.*

Salts of Quinine in Typhoid Fever.—G. Basile publishes the results of the treatment of twenty cases of typhoid fever by the use of salts of quinine, used by stomach, except when the quinine was rejected by vomiting, when the hypodermic method was made use of. Different salts of quinine were used with identical effects. Drinks acidulated with hydrochloric acid were given at the same time to facilitate the absorption of the quinine, and antithermic baths were used. The author concludes his observations with these results: There are no inconveniences from the use of this drug in properly selected cases: It assists the physical antipyresis in reduction of temperature, but he considers the latter preferable; it does not shorten the duration of the disease. Hence he does not find confirmed the observations of various modern authors who would have us think that with the use of this drug we are about to enter upon a new era in the treatment of typhoid.—*Il Policlinico.*

Experimental Arteriosclerosis by Adrenalin Inoculations and the Effect of Potassium Iodide.—W. Taylor Cummins and P. S. Stout in their second set of experiments used a series of six rabbits. These animals all received adrenalin. The first two as controls received that drug alone. The third and fourth rabbits were given inoculations of potassium iodide immediately following the adrenalin, in order to overcome directly the effects of the latter drug. The last two animals were to receive no iodide until the first two had died with manifestations of arterial disease. Number one was emaciated when the inoculations were begun and died after receiving the tenth. Number two died after receiving thirteen inoculations of adrenalin. Number three died after thirteen inoculations—adrenalin and potassium iodide. Number four died after thirteen inoculations, having received the same amount of adrenalin and iodide as did number three. After the death of the first two animals iodide was commenced in the case of number five and six. Later these two animals were killed. At post mortem number one showed a small atheromatous plaque in the arch of the aorta. Otherwise the vessels were normal. Number two had a rather large plaque in the same location. The aortas of numbers three and four were free of sclerosis. In number five there was extensive disease from the aortic cusps to the bifurcation of the aorta. Number six showed several small plaques along the thoracic aorta. The writer's state tentatively that potassium iodide may be effectual in preventing the development of arteriosclerosis after the inoculations of adrenalin. It seems probable that the iodide has no effect in its otherwise absorptive properties after the arteriosclerosis has once appeared.—*University of Pennsylvania Medical Bulletin.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, January 26, 1907.

THE PUBLIC HEALTH DEFENSE LEAGUE.

A BILL has been introduced by Senator Agnew before the Legislature of this State providing for the incorporation of a national society with the above title, under a special charter patterned after that of the Red Cross Society. As set forth in the charter, the purposes of the League will be "to obtain and disseminate accurate information concerning practices and conditions of every kind that are dangerous to the public health and morals, and to work for the enlightenment of the public on all matters affecting these subjects; to work for the enactment of laws in the United States, Territories, and colonial possessions, for the protection and preservation of the public health and morals; to assist the constituted authorities in the enforcement of all laws affecting the public health, including the laws for the prevention of quackery, charlatanism, and criminal practices in the healing art; the prevention of adulteration and substitution of drugs and food substances; the prevention of the sale of narcotics, alcohol, and dangerous substances of every kind, whether under the guise of proprietary remedies and so-called patent medicines and nostrums and remedies, or whether sold as narcotics in violation of law; the prevention of admission to the United States mails of all newspapers and printed matter of every sort advertising any business injurious to the public health or morals; and to prohibit the advertising of such business in any way; to oppose and work against the passage of laws detrimental to the public health and morals; to work for the repeal of any law having such an effect; and generally to institute proceedings in law and equity to carry out the objects and purposes of the corporation."

While the Medical Society of the County of New York has through the activities of its members and counsel been one of the moving forces which led to the incorporation of the League, prominent medical bodies in all parts of the country have allied themselves with the cause in a manner indicative of its importance. Letters approving the call which led to the formation of the League have been received from the American Medical Association, the New York Academy of Medicine, the American Public Health Association, the American Society for Sanitary and Moral Prophylaxis, the American Association of Medical Examiners, the American Medical Editors' Association, and many others. Prominent individuals from all parts of the country have also identified themselves with the cause, and the League will number among its vice-presidents such men as Attorney General Bonaparte, Cardinal Gibbons, Luther Burbank, and others.

The operation of the League will be directed by an executive committee of six members elected from the board of thirty-six directors. This executive committee will meet as often as necessary, to receive the reports from and direct the work of its agents. Each sphere of activity as indicated in the charter will be the special field of a standing committee, and these committees will be assisted by experts in law, medicine, chemistry, and all other lines.

The possibilities for good of a society of this kind are incalculable, and the League, working along the lines sketched in the charter, will deserve the hearty support of the medical profession of the country. The Medical Society of the County of New York has long been active in the pursuit of quacks, and has done good work in keeping down the number of medical parasites in this city, but its work, being conducted by a society of medical men, has not received the measure of public support which is necessary in such an undertaking. The League, essentially a lay organization and of national scope, can carry on this purifying work more effectively, and the results will be naturally more far-reaching than those of the labors of any local organization. We bespeak for this society the cordial approval and cooperation of the medical profession.

ACCIDENTS FOLLOWING THORACENTESIS.

EXPLORATORY puncture of the thorax is so frequently resorted to, and the results of the operation are so generally satisfactory, that the possibility of accident is hardly considered. Accidents do occur, however, of varying degrees of severity, and there may even be a rapidly fatal result. The removal of quite moderate amounts of fluids is well known to have produced sudden death, but the fact that this may also follow simple exploratory puncture is not so well known. Some ten instances of this accident have already been reported, in eight of which a consolidated lung was the cause of the ambiguous signs, having been punctured by the needle. The explanation which has been accepted in most of the cases is that the sudden syncope is due to afferent impulses conveyed to the medulla along the vagus nerve, the terminal fibers of which have been rendered unduly sensitive by compression or inflammation. Russel, who advances this theory, considers that the pulmonary fibers are a more likely source of the impulse than the pleural. Death may be preceded for several days by unconsciousness or convulsions, due to the cerebral anemia produced by cardiac inhibition and extreme lowering of the blood pressure. That there are other causes which bring on sudden death in these cases is shown in one reported by G. G. Sears in the *American Journal of the Medical Sciences* for December, 1906, in which the exploring needle could hardly have reached the pulmonary branches of the vagus, and a subsequent autopsy showed that the two surfaces of the pleura were separated by a considerable layer of fluid. The patient presented a pleurisy with effusion, and aspiration had already been performed. When this

operation was resorted to a second time the man immediately collapsed, becoming cyanotic and almost pulseless. He died fifteen hours later and there were no evidences of any cerebral lesion.

Another accident which may result from thoracentesis is the production of a pneumothorax, of which a moderate number of instances have been reported, including four recent ones by Sears. The latter thinks that the comparatively small number of cases recorded by no means represent the frequency with which the accident probably occurs in practise, and he suggests that it often escapes recognition, as the patient usually recovers. Where a doubt exists it may be cleared up to a large extent by a use of the *x*-rays. When a fatal issue ensues it is probable that the pneumothorax did not contribute to this result, as there are ordinarily a sufficient number of other factors to bring this about. Various theories have been proposed to account for the accident, among which may be mentioned the entrance of air through the aspirating pump or an unguarded needle.

The causes of pneumothorax just enumerated may be avoided by a more careful attention to technique, but there seems to be no way of overcoming the danger of puncture of a solid lung by a needle used for diagnostic purposes. The fact should serve as a warning, however, against the reckless use of the exploring needle before the resources of a physical examination have been exhausted. When fluid is to be removed, the dangers of a pneumothorax may be avoided by allowing the fluid to drain away very slowly, and not insisting that every drop be evacuated. Especially in chronic cases, where the lung does not expand promptly to take the place of the evacuated fluid, the precaution should be observed. Sears thinks that siphonage is decidedly safer when the effusion is large or has existed for a long time, and refers to Forlanini's method as being still safer, according to which sterile air is introduced to replace for the time being the fluid removed.

THE MENINGOCOCCUS AND THE GONOCOCCUS.

The exact status of these two organisms towards each other has long been a problem that has occupied the attention of bacteriologists, and recent developments appear to show that the interrelationship is a very complex one. Ruppel has succeeded in showing that it is possible to obtain by means of cultures of the gonococcus an immune serum which is not only specifically but quantitatively equal in protective power against virulent meningococci to specific meningococcus serum itself, while, on the other hand, meningococcus sera can be obtained which are specific against gonococcal infections. Bruckner and Cristéanu have produced a gonococcus immune serum from horses which was equally agglutinating for gonococci and for typical meningococci. The same authors have also shown that gonococcus and meningococcus immune sera possess precipitins for the bacteria-free products of both varieties of organisms. It therefore appears that gonococci and meningococci produce agglutinins, precipitins, toxins, and antitoxins of the same character.

In view of this discovery considerable interest attaches to some experiments reported in the *Berliner klinische Wochenschrift*, December 31, 1906, by Zupnik, who with four other physicians inoculated the urethra with meningococci. In one experiment several loops of a pure culture of a typical meningococcus were put into the urethras of two of these gentlemen, but only an evanescent local irritation was caused which had subsided completely within twenty-four hours. Then a growth of meningococci of a strain which bacteriologically could not be distinguished from the gonococcus was inoculated into the urethra of a physician who had never suffered from gonorrhea. The result again was negative. In the third experiment meningococci contained in the still warm cerebrospinal fluid of a patient who in addition to the meningitis was also suffering from acute gonorrhea were introduced into the urethras of two physicians, one of whom had had and the other of whom had not had a previous gonorrheal infection; the result of this experiment was also negative, although the fluid contained numerous cocci in every microscopical field. While the negative result obtained in these experiments is perhaps not very astonishing from the clinical standpoint, the demonstration of the fundamental difference in pathogenicity of the two organisms is certainly very interesting, in view of the other evidences of relationship that they can be made to manifest.

FUNCTIONAL ALBUMINURIA IN ATHLETES.

In a recent paper read before the Medical Society of London, W. Collier presented the results of his experience in examining Oxford students as to their fitness in taking part in athletic contests (*Lancet*, December 15). He found it necessary to "advise far more men against submitting themselves to the strain because of pronounced albuminuria than on account of any weakness in either the heart or the lungs. For the past twenty years at Oxford, almost every term, he had examined men, apparently in the very best of health, whose urine would, after athletic struggles, contain a very definite amount of albumin. After a night's rest all trace of albumin would have disappeared. In the past he had advised these men to give up hard athletic competitions, and his opinion had over and over again been endorsed by London consultants. He now believed that this advice was quite unnecessary and therefore wrong. Last February he had examined specimens of urine of 156 undergraduates training for the 'Torpids,' and had found that with the cold nitric acid test eighty-one specimens showed a very definite amount of albumin, or 51 per cent. Of this year's Oxford University crew, after rowing a trial from Putney to Mortlake, every member's urine contained albumin; half the crew's urine contained a very large quantity of albumin. The same thing occurred in the case of the 'Torpid' crews; specimens examined of crews who had been rowing a full course almost invariably showed albumin, and frequently a very large quantity. In the case of the running men, the quantities of albumin thrown down were even more pronounced. In view of these facts Dr. Collier argued that it was no longer necessary to advise men to give up athletic competitions because of albuminuria, and that just as they might expect to find a physiological hypertrophy of the left ventricle and emphysema of the lungs in the athlete, so they might expect to get a physiological albuminuria.

He further asked whether the insurance societies ought any longer to refuse to consider the acceptance of the lives of young men between the ages of twenty and thirty years whose urines had been found to contain albumin after exercise when it could be shown that no albumin was present after rest and after a meal." In the discussion following the reading of Dr. Collier's paper there was in the main an admission of the truth of his contention, but it was also shown that persons suffering from transient albuminuria of the nature indicated, died at an earlier average age than those not thus affected.

Further Experience with Opsonins.

Reports are now beginning to come in from various observers relative to the matter of opsonins and the positive value of the new theory. In the *Lancet* of January 5 is a report of a recent meeting of the Manchester Pathological Society, at which Professor A. H. White of Dublin related the results of his experiences of inoculation on the lines laid down by Wright, and explained the necessity of repeated blood examinations in order (*a*) to regulate the size of the dose and thus to eliminate the negative phase effect as far as possible; and (*b*) to determine the length of time its effects lasted. He detailed the effects of surgical procedure on the opsonic index and showed how clinical improvement following a surgical operation where only a part of the disease was removed was coincident with a rise of opsonic index, and that relapse with involvement of a fresh area resulted when a fall in the index occurred. Moreover, he showed that such cases might be completely cured by inoculation, as soon as the opsonic index fell, of suitable and properly interspaced doses of tuberculin. In the course of the discussion, Dr. Loveday showed that an attempt to find a small dose of tuberculin which could be used empirically in all cases failed. Different doses of T.R. had very different actions in the same person. A very small dose might give a curve of opsonic indices very similar to that obtained by too large a dose. In some cases it was really too large and still smaller doses were required, while in others a larger dose gave satisfactory results. There was an optimum dose for each patient only to be determined by frequent observations of the opsonic index. The question was still further discussed by Dr. Ramsbotton, who spoke of the therapeutic use of inoculations of staphylococcus vaccine in certain common affections, and emphasized their value in cases of furunculosis and the severer forms of acne, when the pustular eruption was plentiful and the individual pustules were large, in contrast to the milder cases of acne consisting of a "few spots on the face" which did not seem to yield so readily to this treatment. In quoting the actual cases treated stress was laid on the fact that the opsonic index, before treatment, in the cases of furunculosis and the severer forms of acne, was below normal, whereas in the milder forms of the latter affection the index was about, or just above, normal.

The Appendix and Laparotomy.

It is chiefly the work of American physicians that has brought about the recognition of the importance of appendicitis. Some years ago, according to Osler, the "iliac phlegmon" was believed to be due to disease of the cecum. It is now known, however, that the cecum itself is very rarely affected. Even the condition which used to be called stercoral typhlitis is really appendicitis. In 1883 Pepper described the relapsing form of appendicitis. Fitz in 1886 cleared up the whole subject in his scholarly paper. Willard Parker was the first one to advise early operation. Other American surgeons, among whom are Bull, McBurney, Keen, Morris, Senn, Deaver, and others, have done much in perfecting the technique of the operation. Among the English surgeons, Treves has emphatically advocated the proper surgical treatment of this affection. Justement in the *Annales de la Société Médico-Chirurgicale d'Anvers* of October, 1906, gives an interesting review of the appendix in relation to laparotomy. The ileocecal appendix has no useful function in man. This fact has been proved many times. After the removal of the appendix health and the various functions continue unaltered for years. According to Ribbert, one-fourth of the human race possess an obliterated appendix, principally those between the ages of fifty and eighty years inclusive. In man the appendix has become a rudimentary organ. Rudimentary organs are in general distinguished by their congenital weakness. They are subject to the contraction of maladies, as has been pointed out by Darwin. The human appendix conforms clearly to this rule. The appendix is not only useless, but it is the cause of much trouble in the human organism. The young are most often attacked by appendicitis. Justement has had occasion recently to examine thirty-five appendices which were removed in the course of laparotomies. The normal appendices were found in the youngest subjects. Kümmel of Hamburg in his examination of this organ has found that in many cases it undergoes profound alterations which give rise to only insignificant symptoms. It would seem, then, that the affection of appendicitis is frequent and susceptible to spontaneous cure. But it is not less true that the patients have been in real danger. According to Bovis, appendicitis is at its maximum frequency from the age of twenty-one to thirty years inclusive. Justement thinks that it is logical to conclude that since the appendix is not only useless but also the cause of much trouble it should be removed whenever this is found to be possible during the course of a laparotomy.

The Value of the Cocaine Substitutes.

One of the leading fields of pharmaceutical endeavor seems to include the production of remedial agents which shall serve as substitutes for the drugs from which they are derived because the latter possess, or are assumed to possess, various toxic properties. The whole gamut of well known drugs has been subjected to this so-called purifying process and in most instances, it must be said, without any signal success which might give an excuse for abandoning the original remedy. Not long after cocaine became recognized as one of the most valuable drugs in ophthalmic practice, efforts were made to overcome its toxic properties and other objectionable features, among which were the production of midriasis and paralysis of accommodation, its effect on the intraocular pressure, and the difficulty of obtaining perfectly sterile solutions. A series of derivatives was the result, for each of which perfection was claimed as the ideal local anesthetic. That claims of this kind will not always bear the test of actual practical application is shown in a recent article by Wintersteiner (*Wiener klinische Wochenschrift*, 1906, No. 45), who comes to the defense of cocaine, as regards its employment in ophthalmic

practice particularly, and demonstrates that the supposed disadvantages are largely overestimated. It is admitted that cocaine may exert an injurious effect on the epithelium of the cornea, and when there is a tendency to glaucoma it may also cause unfavorable symptoms. But aside from this there is very little in the character of the substitutes which would satisfactorily balance these shortcomings. As the result of prolonged observation and experiment, Wintersteiner concludes that although each of the numerous derivatives of cocaine may have its advantages, these are not of sufficient moment to cause an abandonment of the original drug. Their acknowledged inferiority in many respects seems to be indicated by the fact that it is sometimes necessary to combine them with cocaine itself in order to obtain the desired effect.

The Early Diagnosis of Carcinoma.

Although through a better understanding of how to interpret the results of analysis of the stomach contents, and especially through the recognition of the importance of searching for occult hemorrhage as suggested by Boas, great progress has been made in the diagnosis of cancer of the stomach, it is still unfortunately comparatively rare for the diagnosis to be made at a sufficiently early stage of the disease to make the prognosis of operative treatment other than doubtful. Modern surgery has established the dictum that the patient should be brought to the operator before there is any palpable tumor, in order to reap the benefits of the technical advances that have been made in this department of operative work, but the problem is still an excessively difficult one. Albu calls attention to the great importance in suspected cases of keeping careful records of the patient's weight, and believes that a steady, even, though slight, loss of flesh from week to week, when taken in conjunction with other suspicious features, such as a diminishing acidity of the gastric contents, is a symptom of the greatest importance. In the *Deutsche medizinische Wochenschrift*, December 27, 1906, he reports two cases in which the diagnosis was made early enough for the laparotomy to reveal tumors of very small size. In one of these the growth was smaller than a walnut, and Albu thinks that it is one of the smallest gastric cancers that has been diagnosticated during life. No doubt an important reason why such early diagnoses are not made oftener is that patients are not apt to consult the physician until their subjective symptoms have reached a considerable grade of severity, and the condition has already passed beyond the opportune stage. By endeavoring to educate the public in this regard the practitioner can do a great deal toward improving the prognosis of gastric cancer.

Treatment of Tuberculous Ulceration.

The successful treatment of laryngeal phthisis by means of sunlight suggests the thought that this therapeutic agent may also be employed in other tuberculous affections of the mucous membranes in which local applications are feasible. In a recent communication by Weisz in the *Wiener klinische Wochenschrift*, No. 46, 1906, a case is described in which, in a patient afflicted with pulmonary tuberculosis with laryngeal involvement, an ulcer developed on the mucous membrane of the lip. This was swabbed with 1 per cent. eosin solution and exposed to the sunlight, but showed no tendency to heal. Treatment with lactic acid was likewise ineffectual. A combination of the two, however, was followed by a very satisfactory outcome. The ulcerated area was first swabbed with lactic acid (25 to 50 per cent.) and the next morning, after the slough had been removed, was exposed to the direct rays of the sun for varying periods. During the course of two months the ulcerated area was thus exposed for a total of eighty hours, and complete cicatrization resulted. The laryngeal lesion was entirely cured by the sunlight alone, but in the other case the combination treatment was necessary in order to remove the slough from the surface of the ulcer, so that the sun's rays could become effective. But in the treatment of laryngeal lesions, where there is much necrotic tissue present, it would appear advisable to resort to a similar measure when a prompt effect fails to appear from the application of sunlight alone.

Cardiac Trauma.

The fact that cardiac disease may be dependent upon a traumatic basis is well shown by a case reported by Roncagliolo in the *Medizinische Klinik*, No. 38, 1906. The patient, a young man, fell from a considerable height and struck on his left side. He sustained a slight cerebral concussion and sundry abrasions, from all of which he promptly recovered. Soon afterward he developed evidences of cardiac disturbance which became progressively worse, and necessitated his entry into the hospital five months later, when a diagnosis of chronic myocarditis was made. Before the accident the patient had always been perfectly well, neither smoked nor drank, so that none of the usual factors in the production of cardiac disease were present. The heart involvement coming directly after the injury made it most probable that the latter served as the direct cause of this condition, and although the case is unusual, it should serve to call attention to the fact that such a complication may occur.

Difficult Labors and Epilepsy.

The search for etiological factors in the production of epilepsy has animated Volland to investigate the subject from the standpoint of obstetrics (*Zeitschrift für Psychiatrie und psychisch-gerichtliche Medizin*, Vol. 63, No. 5). For this purpose he carefully examined 1,500 cases of epilepsy to determine whether the occurrence of abnormal labors had any bearing on the subject. In forty-five cases (3 per cent.) such abnormalities were found, but a thorough search into the facts of the history in each case showed that the disturbances in question constituted a very subordinate predisposing factor in the production of the epileptic seizures, and in all but a very small proportion of cases they could apparently be entirely discounted.

Public Lectures at the Academy of Medicine.—The second meeting of the public lecture series of the New York Academy of Medicine will be held on Thursday evening, January 31, at 8:30 o'clock. The subject of the lectures will be the Public Milk Supply. Dr. Rowland G. Freeman will speak on "The Risks and Safeguards of Public Milk Supplies," the lecture being illustrated with lantern slides. This will be followed by a short address on "The Milk Work of the Department of Health," by Dr. Thomas Darlington, Health Commissioner of New York City. "How Can the Layman Cooperate?" is the title of the third discourse, by Mr. William H. Allen, General Agent of the Association for Improving the Condition of the Poor.

News of the Week.

Medical Legislation in Pennsylvania.—A bill has been introduced into the Pennsylvania Legislature directed toward prohibiting the practice of Christian Science, osteopathy, and other systems of treating the sick outside of the three legally recognized schools of medicine. A counter bill also has been introduced into the Legislature. This is virtually the same as that passed by both branches of the Legislature two years ago, but vetoed by Governor Pennypacker. It provides for the recognition of the eligibility of osteopathic practitioners to take examinations before the State Medical Board in all branches but materia medica, and to be represented on the State Medical Board, and requiring that none shall be eligible for the State Board examinations except persons who have taken a four-years' course at a school or college, and who have a diploma certifying to this fact. Another bill provides for changes in the manner of examining applicants for license to practise medicine, and also contains a provision to the effect that any person offering services as a practitioner of the healing art, without complying with the provisions of the act, without being graduated from a medical school, and passing the examination of the regular, homeopathic, or eclectic examining board, shall be guilty of a misdemeanor. The bill also changes from three to four years the minimum term of study in medical colleges, requires midwives to undergo the same examinations as physicians, authorizes the State Medical Council to revoke the licenses of physicians guilty of unprofessional practices or unduly addicted to narcotics, and increases from $2,000 to $5,000 the biennial appropriation for the expenses of the State Medical Council.

Festschrift Number of the "Annals of Otology, Rhinology and Laryngology."—The issue of this journal for December, 1906, takes the form of a "*Festschrift*," in honor of Prof. B. Fraenkel of Berlin, who recently celebrated his seventieth birthday. It contains nearly fifty articles on topics connected with nose, throat, and ear practice, opening with a congratulatory address to Prof. Fraenkel by Dr. O. T. Freer of Chicago, following which are contributions by Dr. W. Freudenthal of New York on "Bernhard Fraenkel—what he has done for Rhino-Laryngology," and by a bibliography of his contributions to medical literature by Dr. Freudenthal and Dr. Landgraf of Berlin. Several of the remaining contributions have already appeared in other journals, but the issue is a notable one, and reflects great credit on the Editor-in-Chief, Dr. H. V. Loeb of St. Louis.

Typhoid Fever.—What is considered the most serious outbreak of typhoid fever that has occurred in Philadelphia since that of 1898-9 is in progress in that city. There are said to be more than 1,500 cases in the city, of which 500 are being treated in hospitals, all of which are overcrowded. Last week 342 new cases and 27 deaths were reported. The epidemic is attributed to delay in finishing the city's filtration system, upon which millions of dollars have been spent. In Scranton the morbidity from typhoid fever is diminishing, but both diphtheria and scarlet fever are very common.

Scarlatina and Diphtheria in Chicago.—Both of these diseases are epidemic in Chicago and its suburbs, and the health authorities have stated that there are several thousand cases at present in the city. In Evanston and Oak Park the schools have been closed on this account.

Census of the Blind.—The New York State Commission to Investigate the Condition of the Blind, which is undertaking an inquiry into the cause of blindness and the means to be taken to assist the blind, is engaged in the preparation of a census of all those so afflicted. It is requested that the names of all blind adults, children, or infants be sent to the secretary of the commission, Mr. O. H. Burritt, Batavia, N. Y. It is the purpose of the commission to obtain data on which to make recommendations to the Legislature concerning the establishment of industrial schools for the blind.

Famine and Pestilence in China.—The foreign relief committee at Shanghai reports that smallpox has broken out in the camp for famine sufferers at Tsingkiangpu, and that on this account the officials have broken up the camp, which had several hundred thousand inmates. The efforts to cope with the situation are said to be hopelessly inadequate, and immense loss of life is expected. The institution of relief work is greatly hampered by the lack of means of communication, and the fact that the wealthy are deterred from making large contributions through the fear of official peculation.

Tea as a Beverage for Soldiers.—As the result of observations made while with the Russian Army in Manchuria, by Col. Valery Havard, Assistant Surgeon General in the United States Army, tea is much more suitable as the routine military beverage than coffee. It is considered easier to transport, preserve, and prepare, and has been adopted by the English, Russian, and Japanese Armies. Col. Havard recommends that it be substituted for coffee in the United States Army rations.

Medical Practice Bill in Massachusetts.—An effort is being made by means of a bill now before the Massachusetts Legislature to restrict or stop altogether the practice of Christian Science in that State. While this sect is not specifically mentioned in the bill, which provides simply for the control of the practice of medicine, it is so drawn up as to militate directly against the Christian Science healers.

Suicide in Vienna.—This center of medical study still retains an unenviable prominence among the capitals of Europe in the records of suicides. In the year which has just ended 425 persons—313 men and 112 women—committed suicide, while 707 men and women attempted unsuccessfully to do so. The victims were of all ages, ranging from an old man of eighty-seven to a little girl of eight years. Sickness was the motive alleged in one hundred cases, unhappy love affairs in sixty-three, family strife twenty-three, satiety of life thirty-three, and poverty thirty-one. Twelve women and one hundred and eighteen men shot themselves, nineteen men and thirty-two women took poison, while ten men and twenty-eight women threw themselves from top story windows, a form of suicide common in Vienna.

Bee-Sting as a Cure for Rheumatism.—To demonstrate the good effects of bee-sting in the treatment of rheumatism, an enthusiastic believer at Middletown, Pa., permitted himself to be stung recently by eighteen Cyprian bees before the Pennsylvania State Beekeepers' Association at the Department of Public Instruction at Harrisburg. The treatment was applied by the State Zoologist, from whose apiary the bees were produced, and he was assisted by a representative of the State Health Department.

Advertising Condemned.—Stringent resolutions were adopted at the quarterly meeting of the

Coles County (Illinois) Medical Society, at Charleston, with reference to the appearance of the names of members of the society in the lay press, in connection with accidents, operations, etc.

Women Doctors in Germany.—Prof. von Bergmann of Berlin is reported to have recently said to a medical editor in substantiation of his opinion that women should not engage in the practice of medicine, that so long as women were unable to beat cooks and tailors at the vocations which women are apt to regard as their own specialties, so long would they be unable to compete successfully with men doctors.

Harvey Society Lecture.—An invitation is extended to those interested to be present at the seventh lecture in the Harvey Society course, which will be given by Professor Edmund B. Wilson of Columbia University at the New York Academy of Medicine, on Saturday evening, January 26, at 8:30 P. M. Subject: "Recent Studies of Heredity."

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize will be made on July 14, 1907. The prize is the income from the bequest of the late Señor Alvarenga, and amounts to about $180.

Plague in Rio Janeiro.—During one week recently there were reported in Rio Janeiro thirty-two cases of bubonic plague, with eight deaths; three cases of yellow fever, with one death, and three deaths from leprosy.

Anti-Noise Bill Favorably Reported.—The Senate Committee on Commerce has authorized a favorable report on the bill authorizing Supervising Inspectors of Steam Vessels to regulate the blowing of whistles. The bill has already passed the House.

Red Cross Relief for Kingston.—The New York State branch of the Red Cross, acting under authorization from Washington, has sent relief supplies to Kingston, Jamaica, to the value of $5,000, and consisting of salt beef and pork, canned goods, and soups.

Overcrowding in Hospital for the Insane.—As a result of the formal inspection of the Pennsylvania State Asylum for the Insane at Warren, made recently by a special commission for investigating the conditions prevailing in the insane asylums of the State, it was found that, while the institution is in other respects most admirably conducted, it is greatly overcrowded. With accommodations for a total of 734 patients, 598 men and 582 women have been crowded within its walls, many patients being compelled to occupy cots in long, narrow, ill-ventilated corridors, with low ceilings. There are only 180 employees to take care of the patients, and as these work in shifts, only a small number are on duty at one time. An infirmary for men is badly needed.

Gift to Philadelphia Hospital.—Mr. P. F. Kernan, a real estate broker of Philadelphia, has given $5,000 to St. Joseph's Hospital for the endowment of a free bed. The money was bequeathed by the late Miss Harriet Richards, to be given to any worthy charity selected by the donor. A similar gift was recently made to St. Mary's Hospital.

Muhlenberg Hospital.—The sum of $1,000 has been contributed to this hospital by Mr. and Mrs. Everett Colby of Orange, in the name of their daughter, Elizabeth Colby, who died last summer.

Bequests to Chicago Hospitals.—Five hundred dollars has been bequeathed to the Michael Reese Hospital, and $200 each to St. Luke's and the Alexian Brothers Hospitals, and to the Home for Incurables, by the will of the late Bernard New.

Cincinnati City Hospital.—The medical profession of Cincinnati, as well as the laity, are indignant over the dismissal of Dr. C. R. Holmes, who was serving in an advisory capacity to the Board of Public Service in regard to the building of the new City Hospital. Dr. Holmes has devoted a great deal of time, money, and ability to the work, and is thus summarily dismissed without any recognition of his services.

Jewish Hospital for Deformities and Joint Diseases.—This hospital, which was opened on November 4, in a building on Mount Morris Park, has been so well filled that it has been found necessary to purchase the adjoining property at 1919 Madison Avenue. The new building, which is a brownstone private house, will be remodeled as rapidly as possible.

Meeting of Chicago Children's Hospital Society.—The annual meeting of this society was held January 6, when $1,300 was ordered to be distributed to the various hospitals where children have been cared for.

College of Physicians of Philadelphia.—This institution has received from Mr. Andrew Carnegie $100,000 towards the erection of its new building, on condition that a like sum be raised, of which $80,000 has already been subscribed.

Annual Meeting of the Illinois State Board of Health.—At a meeting, held January 15, Dr. Geo. W. Webster of Chicago was reelected President of the Illinois State Board of Health, and Dr. James A. Egan, Springfield, reelected Secretary and Treasurer.

Philadelphia County Medical Society.—At a stated meeting held January 16 the following officers were elected for the ensuing year: *President*, Dr. James B. Walker; *Vice-Presidents*, Dr. William S. Newcomet, Dr. Joseph O'Malley, Dr. Wendell Reber, Dr. Robert H. Chase, Dr. Maurice J. Karpeles, and Dr. Franklin Brady; *Secretary*, Dr. William S. Wray; *Assistant Secretary*, Dr. Ross H. Skillern; *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. Charles A. E. Codman; *District Censor for the State Society*, Dr. Albert M. Eaton.

The Obstetrical Society of Cincinnati, at its annual meeting, elected the following officers for the ensuing year: *President*, Dr. Wm. Gillespie; *Vice-President*, Dr. M. A. Tate; *Recording Secretary*, Dr. J. H. Landis; *Corresponding Secretary*, Dr. F. S. McKee; *Treasurer*, Dr. L. S. Colter.

Medicolegal Society.—At its annual meeting, held January 10, this society elected the following officers: *President*, Mr. Clark Rice; *Vice-Presidents*, Dr. J. Mount Bleyer and Dr. W. B. Fletcher; *Secretary*, Mr. John R. Abarbanell.

Winnebago County (Ill.) Medical Society.—Officers were elected as follows at the annual meeting of this society, held in Rockford on January 8: *President*, Dr. T. H. Cellane; *Vice-President*, Dr. W. E. Park; *Secretary* and *Treasurer*, Dr. R. C. Bourland.

Dubuque (Ia.) Medical Society.—The following were elected as officers at the recent meeting of this society: *President*, Dr. W. P. Slattery; *Vice-President*, Dr. F. J. Wieland; *Second Vice-President*, Dr. Kearney of Farley; *Secretary*, Dr. Mary Killen; *Treasurer*, Dr. Lily Kinnier.

Buchanan County (Mo.) Medical Society.—At a meeting of this organization, held on January 9, officers were elected as follows: *President*, Dr. O.

G. Gleaves; *Vice-Presidents*, Dr. W. J. McGill and Dr. S. F. Kessler; *Secretary*, Dr. Chas. W. Fasset; *Treasurer*, Dr. J. M. Bell.

Western Massachusetts Ophthalmological and Otological Society.—A society with this name has recently been formed, and the following officers were elected at a meeting held in Springfield: *President*, Dr. Clarence R. Gardner of Northampton; *Vice-President*, Dr. Charles R. Chapman of Springfield; *Secretary* and *Treasurer*, Dr. V. J. Irwin.

York County (Me.) Medical Society.—At the thirteenth annual meeting of this society, which was held in Biddeford on January 9, officers were elected as follows: *President*, Dr. M. H. Ferguson, Biddeford; *First Vice-President*, Dr. O. W. Pillsbury, Saco; *Second Vice-President*, Dr. R. S. Gove, Sanford; *Secretary*, Dr. C. E. Thompson, Saco; *Treasurer*, Dr. H. L. Prescott, Kennebunkport.

Obituary Notes.—Dr. Henry Kost of this city died on January 12, at the age of seventy-six years. He was a native of Germany, and received his medical education in the universities of Jena, Würzburg, and Vienna. In 1855 he held a commission as assistant surgeon in the British-German Legion, and served through the Crimean War; later he held a position in the German hospital at Dalton, England. In 1868 he came to this city, and had practised here ever since.

Dr. Lyman A. Noyes of Chicopee, Mass., died on January 10, at the age of sixty-seven years. He was born in Tunbridge, Vt., and received his medical degree from the University of Pennsylvania in 1862. During the Civil War he served as surgeon with the Second Vermont Volunteers and the Nineteenth Pennsylvania cavalry. In 1880 he was appointed post surgeon at Seal Island, Alaska, but of late years he had spent his winters in Chicopee.

Dr. John J. Blacklock of Morrisburg, Ont., died on January 9, at the age of eighty-three years. He was a son of Dr. Ambrose Blacklock, a surgeon of the Royal Navy, and was born at Williamstown, Glengarry. He was a graduate of McGill University, and had served as coroner of the United Counties for over forty years.

Dr. W. M. Crawford of Lancaster, S. C., died suddenly of heart-disease on January 9, at the age of forty-six years. Dr. Crawford was graduated in medicine from the Charleston Medical College, and had practised in Lancaster for many years.

Dr. R. H. McDonald of Pittsburg, Kansas, died on January 9, at the age of fifty-three years. He was born in Hallsville, Mo., and was graduated from the Marion Sims Medical College in St. Louis thirty-three years ago. He practised for some years in Colorado Springs.

Dr. J. W. Johnson of Torrington, Conn., died on January 12 of typhoid fever, at the age of forty-two years. He was born in Pikesville, Md., and received his medical education in the College of Physicians and Surgeons, Baltimore, being graduated in 1892.

Dr. J. S. Clements of Edison, Va., after a protracted illness, died on January 13, at the age of eighty-three years. He was one of the oldest physicians in the State, and had retired some years ago.

Dr. E. M. Shaw of Victoria, Tex., died recently of heart-disease, at the age of forty-seven years. He had practised in Victoria for about twelve years.

Dr. Solomon D. Meredith of Carthage, Mo., died on January 10, at the age of thirty-eight years. He came to Missouri in 1898, and began practice at Ritchey. Four years ago he removed to Carthage.

Dr. R. B. Price of Kingston, Ont., died in Chicago on January 4 of pneumonia, at the age of sixty-nine years. He was a Queen's graduate, and had practised in Bath, Kingston, and Lonsdale.

THE SIXTH HARVEY SOCIETY LECTURE.

The sixth lecture of the Harvey Society's present series was given by Prof. F. G. Benedict of Wesleyan University on Saturday, January 12, at the Academy of Medicine, the subject being "Metabolism During Fasting." It had been planned to have present the professional Italian long-period faster, Succi, who was subjecting himself to experimentation by Prof. Benedict, but he had been compelled to return abroad. However, one of the speaker's subjects on whom numerous observations in fasting periods as long as seven days had been made, was present at the lecture, and informally discussed his experiences at the close of the meeting. Prof. Benedict confined himself for the most part to describing the experiments completed under his direction on normal fasting men. Owing to the immense expense involved in the undertaking the work was being done under the auspices of the Carnegie Institution of Washington, and the results would appear in the publications of that body.

It had been found, the speaker said, that in adults living under normal conditions there was a constant replenishing of the fats, carbohydrates, and proteid burned for the production of bodily energy or resulting from the wear and tear on the tissues. In inanition, where such a replenishment was not possible, there was a marked loss of weight from day to day. If water was available this loss represented the destruction of the body's store of proteid, carbohydrate, and fat, from which was obtained the energy necessary for the continued existence of life. Extensive observations had been made in the study of metabolism under these circumstances, but attention had been devoted for the most part to the catabolism of proteid as indicated by the nitrogenous constituents, and by the sulphur and phosphorus of the urine. This gave a rather one-sided view of the subject, since the metabolism comprised as well the utilization of fat and carbohydrates. This method would have to be supplemented by a study of the heat production. Luciani and also Tigerstedt had had fair success in studying metabolism in the more complete manner, but their experiments were more or less interrupted, and had not the completeness and the refined accuracy of the observations made in the respiration calorimeter chamber at Wesleyan University. This calorimeter chamber, as perhaps all knew, had been constructed and perfected under the direction of Prof. Atwater, who, had conducted numerous noteworthy nutrition experiments by means of it. (There was a similar apparatus, the speaker said, at the Pennsylvania State Agricultural Station, where nutrition studies were being carried out on the large domestic farm animals.) The calorimeter chamber consisted of an air-tight, copper-lined box, ventilated by forcing a current of air through by means of a blower. As the air left the chamber it was passed through concentrated sulphuric acid to remove the moisture, and then through jars containing soda and quick lime to absorb the carbon dioxide. The quantities of carbon dioxide and water eliminated by the subject under observation for any given time could then be determined by the increase in weight of the acid and the soda-quick lime jars. The deficiency of oxygen in the air was made up by replenishing from cylinders of oxygen gas; the oxygen consumption there-

fire was a known factor. In order to prevent loss, through radiation and conduction, of the heat given off by the subject, *i. e.* to make the chamber a calorimeter, there were two walls outside the copper lining; one was of zinc, the other of wood, and there were air spaces between. The chamber was cooled by passing cold water through a series of tubes in copper discs, which served as heat absorbers. From the amount of water passed through in a given time and its increased temperature, the loss of heat by the man in the chamber could be calculated. Access and communication to the interior of the chamber was through a small double window. The chamber contained a telephone, a chair, a couch which folded up against the wall, a chair which could be suspended from an exterior scale, so that the body weight could be determined, and finally, if desired, a bicycle machine for exercise tests. Respiration and pulse of the subject were recorded on a smoked drum by a pneumograph with a long rubber tube connection, and the individual's temperature was recorded by an electrical resistance thermometer retained constantly well up in the rectum, and connecting with the outside world by wires.

The subjects were students and young professional men. The calorimeter was entered some hours before the beginning of the experiment. During the stay in the apparatus there was a more or less prescribed routine of life, with little muscular work. The only thing given was distilled or tap water. In all fourteen experiments had been made lasting, in fasting periods, from two to seven days, and covering an aggregate of forty-three days.

Prof. Benedict gave the main facts brought out by the investigations as follows: The most noticeable thing was the loss in weight, but the values fluctuated, and were not accurate indices of loss of body tissue. The variations were associated with extra elimination or retention of water, and were often considerable, ranging from 44 grams to 1.1 kilos. The average losses on the first and second days were about a kilo, on the third about 787 grams, on the fourth 682 grams, and on the fifth, sixth, and seventh days about 500 grams per day. The body temperature was lower and more constant than in normal individuals. Pulse and respiration tended to be much slower, but the degree of change varied in different individuals. With the resumption of food there was a rise of temperature and a marked increase in pulse and respiration. There was a diminution in the red cells and the leucocytes. Differential counts showed no change in the relation of the various types of cells except for some increase in the lymphocytes. The speaker, however, said that these blood tests were not entirely satisfactory. There was a noticeable falling off in strength as indicated by dynamometer tests; with the resumption of food the strength rapidly returned. After a fast of only two days' duration the body weight was rapidly regained, in fact, the original weight was somewhat exceeded, and remained at the higher level. This fact could be applied practically as a method of increasing body weight. No special discomfort was noted as a result of fasting. It had been noted, however, that a good mental condition was essential for a successful fast. In short fasts the degree of emaciation was slight. No fasting faces had been obtained in any of the experiments.

The nitrogen eliminated daily in the urine varied on the first day from 5.8 to 15.3 grams. It was usually about 10 grams in longer fasts, after the third day. The water output per day in respiration and perspiration amounted to from 600 to 800 grams. The carbon dioxide output was reasonably uniform; it was higher on the first two days and then gradually diminished. While this figure was an approximate estimate of the total oxidation, the oxygen absorbed was a much more exact measure. The proteid catabolized was essentially represented by the N output (times 6¼) in the urine. Knowing the CO_2 given off, the oxygen absorbed, and the nitrogen of the urine per day, it was possible to calculate the amounts of fat and carbohydrate burned. At rest during inanition it was found that about 150 grams of fat was utilized; but before this the glycogen store was drawn upon, 181.6 grams having been utilized. Later the glycogen used might be as low as 20 grams per day. The amount of heat produced was largest on the first day, and tended to diminish. It was not far from 1800 calories, though with absolute muscular rest probably about 1500 calories. A day of sleep would amount to about 1300 calories, as shown by calculations based on six-hour periods. In different individuals the heat production was apparently parallel to the pulse rate. A balance between the heat produced and the energy as calculated from the oxidations gave close results, showing the reliability of the deductions.

The rest of the lecture was taken up with a description of the detailed results of a single seven-day fasting period. The results were essentially those given above.

At the conclusion of the lecture, the chairman, Prof. Graham Lusk, announced that the studies of Prof. Benedict would probably be extended to observations of various pathological conditions. These would doubtless throw much light on some still very obscure metabolic disturbances.

Correspondence.

TRYPSIN FOR THE CURE OF CANCER.

To the Editor of the Medical Record:

Sir:—Replying to Dr. Morton's letter appearing in the Medical Record of January 19, 1907, commenting on my "facts," I would like to make the following observations

It is very refreshing to learn that Dr. Morton is willing to admit that one-third of my claims are founded on fact, and that in so far his statements were not strictly correct.

In answer to Dr. Morton's statement, substantiated by the unreliable letter of the patient, to the effect that I did not "attend the patient at her home and did not examine her during this time, except at my (his) office, and in the early stage of treatment," I have to say that, during the seven weeks in question, I examined the patient at her home, and with her consent measured the tumor to learn what were the effects of the *x*-ray in the hands of a specialist. The period in question is the seven weeks following July 3, when the patient first visited Dr. Morton. The dates of my visits were July 3, 6, 7, 10, 14, 17, 21, 24, 28, 31, and August 4, 7, 10, 11, 14, 16, 18, 21, 23, 24, 25, 28, and 29. I stated in my letter that the tumor increased or decreased in size according to the menstruation. I drew a diagram of the tumor July 7, when largest diameter was four inches; diameter at right angles to this was three and one-half inches. July 14 the patient menstruated, and the tumor measured in the same diameters nearly one-half inch larger. After that the tumor diminished in size till August 4, when it began to enlarge, and remained larger till menstruation again occurred, when it began to diminish in size. Perhaps even Dr. Morton will believe that I had opportunities to make these "careful notes" when I state that from them I am able to tell him what drugs he or his associate gave the patient, who showed me the prescriptions.

Dr. Morton asks what has this to do with trypsin. In my first letter I avoided any discussion of trypsin, saying that I was using it, as are many other men. Trypsin doubtless furnishes certain ferments which enable the body to assimilate more of the food taken, thus prolonging the struggle between the tissues and the cancer. My purpose in writing these communications is to guard against hasty and misleading conclusions in experiments with remedies which follow one another in such quick succession as to be a menace both to the public and to the profession. No

personal animus actuates my letters, but a conscientious desire to record my observations for the value other surgeons may find in my experience.

EDWARD W. PEET, M.D.

HYOSCINE AND SCOPOLAMINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD of January 12 is an article by Dr. Birchmore, of Brooklyn, on "The Hyoscine Sleep in Obstetric Practice," in which the writer warmly advocates the use hypodermically of morphine and hyoscine hydrobromate as a means of producing profound and anesthetic sleep during the painful period of labor; this he recommends as being "without risk to mother or child." In the latest revision of the U. S. Pharmacopœia, hyoscine hydrobromate is said to be identical with scopolamine hydrobromate, and the latter is said to be identical with the former. Potter, in his "Materia Medica," seventh edition, page 340, says "nearly all the hyoscine hydrobromate supplied by manufacturing chemists consists of scopolamine hydrobromate (Schmidt)."

A number of articles have recently been published on the use of morphine and hyoscine hydrobromate in obstetric practice, and in every instance the procedure is recommended as being perfectly safe. From the number of deaths reported from the use of morphine and scopolamine hydrobromate anesthesia, which have caused it to fall quickly into disrepute, I feel that attention should be called to the identity of these drugs before we begin to hear of accidents from this anesthetic which is "without risk."

H. W. CHAPMAN, M.D.

WHITE HALL, ILL.

A COMPLETE EDITION OF THE ANCIENT GREEK MEDICAL WRITERS

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the Greek journal, *Medical Progress*, the editor, Dr. J. Phoustanos, writes: "The complete edition of all the ancient Greek medical writers which we have been preparing for many years will go to press within a few months, all the preliminary work being accomplished. We give this good news to our readers, who, for a very insignificant amount, can acquire now a complete and most precious library in which will, within a few years, be collected all the works of the ancient Greek physicians, not only those already published and of which some are out of print and difficult to obtain, but also some which exist only in old manuscripts and will now appear in print for the first time. The attempt of this publication involves enormous expense, but it will honor greatly our country to which alone belongs the right to preserve and to transmit thus the admirable work of some of her best men. We hope that this undertaking will be brought to a successful end by the aid of Greek physicians in all parts of the world, who will thus bring honor on themselves and on their country."

I know from Dr. Phoustanos that he began the preparation of this edition about ten years ago, and has had the assistance of the leading medical men and philologists of Greece in the work. The patriotic men of science who cooperate with Dr. Phoustanos are not only honoring their country, but render an exceptional service to true lovers of science all over the civilized world.

A. ROSE, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ARMY MEDICAL ARRANGEMENTS—MANAGEMENT OF NATURAL LABOR—JOURNAL FOR TUBERCULOSIS—APPENDICITIS—LIVINGSTONE COLLEGE—INQUESTS—OBITUARY.

LONDON, January 4, 1907.

THE army would seem to be always in need of reorganization—or is it rather that every new war minister thinks he must alter what his predecessor has done? Not a few officers complain that the force suffers from these constant changes, and some of them say it is just a round of meddling and muddling. When one considers the subject attentively it does seem remarkable that every civilian who takes the responsible office of a minister seems to imagine himself at once qualified to set at nought the views of military experts. It accords with our parliamentary system to set a politician over the army that he may be responsible to parliament for administration, but it is an abuse when a civilian is permitted to override the judgment of the most distinguished soldiers without stating in writing his reasons for such supersession. The medical department of the army is dealt with on similar lines, and it is now officially stated that the War Secretary has decided to reconstruct the advisory board and to make it more distinctly advisory in its functions. This probably means that the politicians shall be at liberty to set aside the advice of the medical board without question. It would be no novelty were such the intention, and the way in which former administrations have been ignored is not encouraging. Still it is possible that Mr. Haldane may intend to follow the advice of his reconstructed medical board, in which case he should see that his successors in office shall be compelled to do so or to record their reasons for not doing so. The necessity of leaving a record for the guidance of their successors would be a most valuable safeguard against the propensity to meddle and muddle. If Mr. Haldane is in earnest he might gain the confidence of the department by replacing its director-general on the army council. His new advisory board is to have that officer for chairman, and he could represent the opinions of it with authority and explain its recommendations to the council as occasion might require. The other members are a civil sanitary expert, a civilian physician, a civilian surgeon, an officer of the R. A. M. C., with special knowledge of tropical diseases, an officer of the R. Engineers, the president of the Indian Medical Board, and the deputy director-general, who will act as vice-chairman. The Army Hospital and Sanitary Committee is to be dissolved and its duties transferred to the Medical Advisory Board. An officer of the R. A. M. C. is to be appointed to act on the staff of the inspector-general of the forces, as an inspector of hospitals and army sanitation.

The management of natural labor is a subject of interest to every practitioner and which it might be supposed is well understood in this century. It came up for consideration last month at the Harveian Society and produced some interesting observations. Dr. Boxall opened with a reference to the mortality in lying-in hospitals thirty years ago, which then averaged fourteen per cent. This rate has greatly diminished, but it is still high in cases treated in hospital, the main cause being, according to Dr. Boxall, septic absorption from lacerations, or the use of instruments or imperfect methods of employing antiseptics. It was, he said, not merely the use, but the proper use of antiseptics which had led to such a great improvement in statistics of hospital cases. Training in the use of antiseptics he declared to be as necessary for students as for midwives or nurses, and neglect of such training might account for the comparatively high mortality of private cases.

Dr. Horrocks said that 100 years ago pyrexia after delivery was the rule, and lying-in hospitals were hotbeds of infection. The proper use of antiseptics had effected a great improvement. Syringing was tried, but abandoned when it was seen that the hand of the accoucheur introduced septic material. He thought nature managed delivery better without artificial aids. He did not approve of chloroform or the use of forceps unless absolutely necessary. Even with strict antiseptic precautions forceps might produce lacerations or tears, which gave trouble later on. At Guy's Hospital forceps were resorted to only in four or five per cent. and the mortality was low. He did not consider gonorrhea gave rise to puerperal fever, though it did to ophthalmia neonatorum, but he depreciated the routine dropping of irritating lotions into the eyes of newborn children, for in the absence of gonorrhea they set up ophthalmia.

Dr. H. Phillips said his case mortality was only one per cent. He usually examined more than one, but used strict antiseptic precautions. He left delivery as far as he could to nature, only douched after instrumental delivery and then only once.

Dr. Adams disapproved of chloroform as having a marked effect in diminishing the pains and as often necessitating the use of instruments.

Dr. Bluett said rupture of the perineum should not often occur, even in primiparæ, when forceps were used or sufficient care was taken.

Dr. Payne asked about the use of ergot as a routine measure.

Dr. Handfield-Jones referred to the difference between hospital and private cases. He found chloroform seldom necessary in hospital, but often beneficial in private practice. In moderation it did not interfere with the progress of the first and second stages, in the third it might prevent rupture of the perineum. So with ergot, seldom required in hospital, but often in private cases. He could not agree with Dr. Boxall as to deficient training of students in the use of anti-

septics, for statistics showed that the mortality of cases treated at their own homes by students at the large hospitals was very low. Where high mortality occurred was in the unsanitary surroundings of the poorest classes, and still more fatal was examination by ignorant midwives, who infected patients before they were seen by a doctor.

Dr. Lewers said vaginal examination was a source of risk, as it was impossible to render the hands absolutely aseptic. It was therefore desirable to make out the position of the child as far as possible by external examination. When it was possible sterilized rubber gloves should be worn. Some cases of sepsis occurred in spite of all, perhaps from organisms from the vulva, by douche or finger.

Dr. W. F. Cock (president) said most cases of sepsis were due to infection by a midwife. He said to all: "Mark well your hands—there the danger lies."

The *British Journal of Tuberculosis* has made its appearance as a quarterly under the editorship of Dr. T. N. Kelynack. Contributions from our leading authorities on the subject are included in No. 1.

Sir James Sawyer attributes the increase of appendicitis of late years to chips of enamel from cooking vessels getting into the food and finding their way to the appendix. He says the enameled cooking ware came into use coincidently with the increase of appendicitis. An eminent medical friend of mine used to assure me that tomato seeds were the real culprits, and he arrived at his conclusions by precisely the arguments put forth by Sir James Sawyer. Tomato seeds are very hard and indigestible. It is known that they will pass unchanged through the bowels, but neither they nor enamel have, I think, been found in the appendix.

The report of Livingstone College for last year has been issued. It appears that there is a larger deficiency than in the previous year, perhaps due to a special appeal in the latter. Mr. J. Cantlie, editor of the *Journal of Tropical Medicine*, who has had long experience in the tropics, has emphasized the advantages of the training at the college, and the report says: "If only Mr. Cantlie's views were fully understood and acted upon Livingstone College would soon need to enlarge its borders."

The Imperial Cancer Research Fund has received a donation of £40,000 from Mr. and Mrs. Bischoffsheim, who have chosen this method of celebrating their golden wedding.

At an inquest this week on a laborer who died of consumption evidence was given that he doctored himself, as he had no faith in doctors. Asked what he took his widow said anything he was told of. The last thing he tried was an inhaler for the nose, for which he paid 3 guineas and 8 shillings a bottle for the fluid. It was said the whole lot would not cost more than three or four shillings. The coroner said he had had many cases in which credulous people were deceived by quacks. They saw the government stamp on quack medicines and thought it was a guarantee. The government gained by the stamps, but the public were deceived.

The death of Dr. Andrew Balfour, J.P., on the 26th of December, at the age of fifty-seven, has cast a gloom over the district of Portobello, and indeed of all Edinburgh. He graduated in 1873 as M.B., C.M., and proceeded to M.D., 1877. He had a large family practice and held many appointments in his district but his energies were also directed to all philanthropic work in the district. He was president of the Workingmen's Institute and directed its Sunday Bible class. He founded a branch of the Boys' Brigade and organized other valuable social and religious efforts, and has left a name which will long be cherished by his fellow citizens.

Dr. Herbert Kendall, F.R.C.S., surgeon to the Royal Hospital for Children at Bristol, died on December 22, aged only thirty-nine. He was busily engaged in his practice when he was attacked with abdominal pain and high temperature. There was some abatement of symptoms, which proved deceptive, and in a few days operation became necessary. This was successful, but pulmonary symptoms followed and he died unexpectedly of thrombosis. He was described by his pastor at the funeral as "the friend of all who knew him, true, able, highminded, strong, and tender, very fit for life or for death."

Dr. T. H. Cheatle, J.P., died on the 15th ult., at Burford, Oxon, where he had spent his professional life, taken part in all social and religious work, and endeared himself to the population far and near. He was in his seventy-sixth year.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

INDIGURIA—FUNCTIONAL EFFICIENCY OF THE KIDNEY—CAUTERIZATION OF THE LARYNX BY ETHER—MUSCULAR ATROPHY AND JOINT DISEASES—UNIVERSAL GIGANTISM—ADENOMA SEBACEUM.

VIENNA, DECEMBER 23, 1906.

A CASE of indiguria has been reported by Dr. Adolph Hecht, who observed it in Escherich's clinic. The patient was an otherwise normal boy, three and a half years old, who, according to the statements of his mother, had not suffered from intestinal disturbances. A few hours before bringing him to the clinic the mother had noticed that the child was passing green urine. Urine voided in the clinic showed the same tinge, though to a less marked degree. The urine was clear, acid, of normal odor, and on standing a green sediment composed of urates and amorphous blue masses was deposited. Chemical examination revealed nothing except a marked indican reaction. On shaking the urine with chloroform the latter acquired a distinct blue color, and the urine became lighter in color while the indican reaction was lessened. The chloroform gave the absorption spectrum of indigo. The occurrence of indigo in undecomposed urine is very unusual. One autopsy reported by Wang appears to show that the oxidation takes place in the kidney; at any rate the cut surface of one of the kidneys became blue on exposure to the air. In the present case it was not possible to demonstrate the presence in the urine of an oxydase.

Interesting observations on renal functions have been made by Dr. Schur. Both pathological and clinical observations indicate that arteriosclerosis is usually accompanied by changes in the kidney. In order to investigate the matter of renal insufficiency, Schur tested the dilution capacity of the organ, that is, the changes in diuresis caused by the administration of water in the healthy, in those with renal disease, and in those with arteriosclerosis. The persons under observation were directed to void at 6 o'clock in the morning, and after that once every hour. At 9 o'clock, one half liter of water was drunk and the urine collected during 3 or 4 hours more. These different specimens were then tested physically and chemically, and the reaction of the kidney to diuretin was also investigated. The following results were obtained: In the normal individuals pronounced diuresis followed the ingestion of the water, so that the entire quantity of fluid had been excreted within four hours, but the process of elimination was delayed in the nephritics, and in most of the persons with arteriosclerosis. The administration of diuretin gave similar results. It was found that in a large number of cases of arteriosclerosis the same conditions were observed as in dealing with nephritics. The chemical examination of the urine did not reveal anything characteristic. While a test of this sort is not of direct value in determining the anatomical disease of the kidney, it is of importance when it is desired to discover any possible disturbance of renal function in cases in which no other evidence of disease is present, for example, in arteriosclerotic changes of the organ. According to the results of these investigations we are justified in referring to renal insufficiency those symptoms which are common to both arteriosclerosis and nephritis, and also in applying the same mode of treatment to both conditions. In explaining the phenomena of urinary secretion and of renal insufficiency, Schur suggests a theory according to which processes of imbibition and deimbibition of the renal epithelium form the most important feature in urinary secretion.

Dr. Menzel has observed a case of cauterization of the larynx by ether during anesthesia. The patient was a man of advanced years, who was subjected to a severe operation requiring ether anesthesia for an hour and a half. The anesthesia was stormy and the patient repeatedly suffered from asphyxia so that artificial respiration became necessary. When the patient became conscious he was totally aphonic and also suffered from dysphagia. Examination of the pharynx showed that the palate and tonsils were reddened, and on inspecting the larynx it was seen that all parts of this organ were swollen and congested, while the vocal cords were covered with a thick white eschar. The pharynx also showed such white patches shortly after the operation so that the possibility of a diphtheritic infection was considered, but evidently these lesions also were the results of the cauterization.

Observations on animals have been carried on during several years by Anton Bum in the Institute for General and Experimental Pathology, in order to determine the mode of causation of the muscular atrophy which nearly always promptly appears after diseases and injuries of the joints. The question is whether these are to be regarded as trophoneuroses or as the consequence of the inaction of the member produced either by pain or the surgical dress-

ing. His experiments seem to show beyond a doubt that the most important part is played by the muscular inaction. Possibly, however, reflex stimuli may be concerned in articular atrophies, but it is a question whether they are of great importance in this connection. While it is true that acute trophoneurotic changes in the skin, hair, nails, subcutaneous tissues, muscles, and bones occur in articular disease, these are not constant, or even very frequent.

A six-year-old boy, presenting universal gigantism was demonstrated by Dr. Knoepfelmacher before the Gesellschaft für Kinderheilkunde. The child has been under observation for three years, and now has a height of 146 cm., the upper extremity has a length of 57 cm., the lower of 67 cm., the hand measures 15 cm., and the foot 16 cm. The entire skeleton is extremely heavy and broad, and the body is developed proportionally in all respects. The musculature is well developed, and the strength is far in excess of what corresponds to the patient's age. Particularly conspicuous is the enormous development of the genital organs, the penis being about 10 cm. in length, the testicles of the size of a pigeon's egg, and the pubic hair being present in abundance. There is no axillary hair, but there is a suggestion of mustache and beard. The child is an imbecile. Examination with the *x* rays showed advanced ossification of the hand and foot, but the epiphyseal lines are still open. Knoepfelmacher considers that the case is one of gigantism secondary to precocious puberty.

Five cases of what is called adenoma sebaceum, Pringle, have been observed by Prof. Riehl. This observer has already pointed out that in these cases there is neither an adenoma nor a disease of the sebaceous glands. Two of the patients were twin sisters, and a similar occurrence of the disease in four brothers and two sisters has already been reported. In most cases the disease has begun in infancy, in others it has commenced at the time of puberty, or in connection with some acute infectious disease. Particular interest attached to two of the patients, a girl and her father, because they demonstrated in a striking manner the hereditary nature of the disease. Three brothers of the father, the daughter, and he himself, as well as his own father and grandfather, suffered from the same affection. The brothers died without leaving any descendants. From his observations in these cases Riehl believes that the underlying condition is a much more deep-seated one than has heretofore been supposed, and he regards it as being embryonal in its inception and becoming manifest congenitally or later on in life. It is an abnormality of structure depending on an inherited tendency. According to this view the other terms applied to the disease, such as nævus sebaceus, or multiple symmetrical facial nevus, do not at all express the true nature of the disease.

OUR LETTER FROM THE PHILIPPINES

(From Our Special Correspondent)

FATAL INOCULATIONS WITH PLAGUE-CONTAMINATED CHOLERA VACCINE.

MANILA, November 17, 1906.

While Dr. R. P. Strong, chief of the Biological Laboratory of the Bureau of Science, was making inoculations with cholera vaccine upon prisoners confined in Bilibid Prison, he was unfortunate enough to use a vaccine that in some way had become contaminated with other organisms, possibly plague. In all twenty-four prisoners were inoculated, and ten have died, all with symptoms which have been attributed to the inoculation. The matter became so serious that the Governor-General issued the following official statement:

"On November 16 Dr. R. P. Strong, Chief of the Biological Laboratory of the Bureau of Science, inoculated twenty-four prisoners in Bilibid Prison with an anticholera vaccine, with which he made inoculations before, and the use of which is well known in several countries in Europe, particularly in Spain, where inoculations of this kind have been made with beneficial results. On November 18 and 19, two and three days after the inoculation, a number of these prisoners became acutely ill, and on the evening of the following day, November 26, two of them died, apparently from the results of the inoculation. Subsequently, on various days, seven more prisoners died in the prison hospital, and one prisoner, whose sentence had expired and who had been released from Bilibid, died on November 21 at 152 San José. These inoculations were made by Dr. Strong under authority dated March 1, 1904, which authority was for 'the carrying on, under the supervision of the Director of the Biological Laboratory, of the investigation among inmates of Bilibid Prison with reference to diseases which prevail among them, as outlined within.' Since this authority was granted, over half the prisoners at Bilibid have been inoculated against cholera without any harmful results whatever.

"All these cases of death were promptly referred to the Coroner for proper action by him, and under his instructions autopsies had been made in each instance. An investigation is now being made under his direction to determine the exact cause of death in each instance, and upon that information being obtained, the coroner will render the verdict required by law.

"It appears that probably these deaths have resulted from the anticholera vaccine which was used, having in some way become contaminated with plague germs while the vaccine was being prepared in the government laboratories. A number of years ago thousands of inoculations with this same anticholera vaccine were made by Dr. Ferrán in Spain, and similar instances of contamination occurred and some deaths resulted. I wish it understood, however, that the accidents which resulted from this inoculation were not due to the method itself, but to the contamination of the vaccine just before final preparation. No test as to whether the vaccine has been contaminated can be made on animals, for the reason that the Ferrán virus must be prepared for use and used while fresh. Immediately after being notified that the prisoners inoculated had become sick, Dr. Strong laid the matter before the proper authorities for investigation and action by them.

"It is needless to say that Dr. Strong is grieved beyond measure at the unfortunate accident which occurred with these twenty-four inoculations. Dr. Strong has made, in the past few years, thousands of inoculations with anticholera and antiplague vaccine, and never before have any untoward results followed. These particular inoculations were made on his own responsibility, under the authority above described, and were in no way authorized by or participated in by the Director of Health or by the Director of the Bureau of Science. I am immeasurably grieved at the unfortunate result of this accident, and it is unnecessary to add that every possible step has been and will be taken by the government to care for the other patients who have suffered from this inoculation, and to relieve, as far as possible, any distress which may have been caused the families of those who have been affected."

Since the statement was made by the Governor-General another prisoner has died, and the thirteen remaining are still in a very serious condition. The cases have all been isolated and every reasonable precaution has been taken to guard against the spread of the infection among other prisoners.

Progress of Medical Science.

New York Medical Journal, January 12, 1907.

The Untrained Nurse; Her Legitimate Field and Her Opportunity for Self-improvement.—J. H. Wiggins discusses the question of nursing as it affects small communities in which the patients are unable to pay the usual city price for nursing. He declares that so far as remuneration is concerned, the city nurses are practically maintaining a trades-union state of affairs in that they are not willing to work for less than twenty-five dollars per week, a price prohibitive for most people in small communities. He believes that there is a field for the nurse who has not had the training of a city hospital and that the correspondence schools for nursing have a legitimate field in supplying the theoretical portion of instruction. The practical portion must be given by the country physician at the bedside of his patients, and he claims that if physicians will take the trouble to do this in case of such women as may show an aptitude for this work, he will go far to solve the question for small communities and make his own work much more satisfactory by developing the material at hand.

The Insanity of Inebriety.—According to T. D. Crothers the term inebriety describes a pathological condition demanding alcohol for its anesthetic effect and refers to some depressed state or psychic condition which consciously or unconsciously calls for relief which alcohol gives with satisfaction. Alcohol is not the cause, but merely a symptom. Hence the condition must be one of disease and organized degeneration. The author then goes on to describe various types of this form of insanity and the proper methods which should be followed in controlling it. He notes that to all ordinary observation a periodical drinker resembles the insane in conduct and rea-

soning. Such persons use spirits to extreme toxic states for a brief period, then rigorously abstain for a while and then relapse. This resembles acute mania in the dominance of the drink impulse overwhelming the mind and body for a period, then subsiding. It also resembles epilepsy in its sudden convulsive onset, and inability to reason and control up to a certain point. Often the periodical drinker is unconscious of the import and meaning of these symptoms. He will suffer from insomnia, headaches, great irritability, intense nervous anxiety, and dread of loss. He will consult physicians, believing he has serious organic diseases, go off on vacations, make changes in his surroundings and business relations, then all unexpectedly, will drink to great excess, when all these symptoms will disappear. In most cases there are distinct premonitions of the drink storm in conduct, reasoning, and appearance, which the friends recognize, but the victim does not. A large class of the periodical drinkers seem to have some consciousness of the coming attack, and use means to avert it. They often go to hospitals and sanatoria, particularly where they have had some experience before, appearing in a state of great fear and excitement, which quickly disappears. The storm is averted for the time being, and such cases are always very hopeful. In many persons of this class of periodical drinkers, the premonitory symptoms take on the form of reasoning manias. Thus they make elaborate preparations in business affairs, providing for their absence during drink attacks. Many of these persons are active in social and religious work, but a period of unusual fervor is often a precursor of a drink storm. Some show great exaltation of mental activity; others take on a different personality while drinking. With some certain atmospheric and electric conditions bring on an attack. In all there is an unstable highly sensitive brain and nerve organization with a tendency to exhaustion on the slightest occasions. A clinical history shows that heredity is a very large factor in this instability and feeble pain resistance, it also shows that injuries, irregularities of living, defective nutrition, sleep, and excessive strains and drains with other causes predispose to a convulsive condition of nerve energy and depression, for which spirits is a grateful narcotic.

The Pathogenesis of Facial Hemiatrophy.—A. Gordon reports a case occurring in a negro male, aged forty-two years. He cannot believe in the exclusivism of the sympathetic origin of the malady, as his own case seems to controvert such a theory. According to some observers a primary atrophy of the subcutaneous cellular tissue is the essential feature of the condition. Others believe that it is of a nervous origin and may follow affections of either the sympathetic, trigeminus, or facial nerves. The majority of cases reported point to an involvement of the inferior sympathetic ganglion. Concomitant pulmonary lesions are found at the apex in many of these cases. This is accounted for by the relations between this ganglion and the pleura at its apex. The author's case presented not only a trophic disturbance of the facial muscles, but also sensory disturbances over the area covering these muscles. That the lower cervical ganglion did not play a rôle in the causation of the disease in this case was evident from the fact that there were no pupillary changes nor vasomotor disturbances on the affected side. It is possible that the sympathetic fibers found in the fifth nerve may play a certain rôle in the disturbance of nutrition of the facial muscles, but association of sensory disturbances and the neuralgic pain in the same area immediately preceding the beginning of atrophy present a strong presumption in favor of the trigeminal pathogenesis of the affection. As to the question of facial nerve it cannot be admitted in this case, as there was no genuine palsy of the affected muscles. The patient had preserved the ability of contracting them, but the degree of contraction was, of course, smaller by reason of the atrophy. The sensory disturbances also were against this view. The author concludes that hemiatrophy of the face may be caused by the lower sympathetic ganglion with its nerve, by the fifth nerve, by the Gasserian ganglion, finally by a central lesion. The tendency of some writers to attribute Romberg's trophoneurosis exclusively to the sympathetic nerve fibers is erroneous.

Certain Diseases of the Peritoneum.—J. G. Mumford considers acute, subphrenic, diffuse, chronic, and exudative peritonitis, chronic adhesive sclerosing peritonitis, and tuberculosis of the peritoneum. He describes the pathological changes in each of these conditions, their symptoms, and gives his own ideas as to the proper treatment of each. Referring to the old medical treatment by opium, he notes its modification by some physicians who limit the dose of opium to that which will allay pain and they give the remedy hypodermatically. They attempt to relieve the intestinal distention by giving high enemata of salts, glycerin, or turpentine; they nourish the patient by enemata or by small quantities of liquids by the mouth; and they allay thirst by allowing the patient to suck cracked ice. The author believes that if a physician proposes to treat a case without operation no such half-way measures are permissible. The proper nonoperative method is to put the intestines at rest by emptying the stomach through lavage, and then keeping it empty. The stomach washing may be repeated if that organ fills up again with material regurgitated from the intestine. After washing out the stomach, put into it nothing until convalescence is established, no water, no food, no cracked ice. Give morphine for pain, if there be pain. Nourish the patient by nutrient enemata, in four ounce doses every four hours. Relieve his thirst by subpectoral infusions of normal salt solution, or by intravenous infusions. Stimulate him with strychnine. Such treatment, heroically followed, often will head off and subdue an advancing peritonitis. Most surgeons, however, are loth to adopt these measures as a routine, because they feel that the fountainhead of the trouble, the local lesion—perforated appendix, duodenum, or whatever it may be—is thus left to keep up its contribution of poison to the peritoneum. The author expresses himself as in hearty sympathy with this latter view.

Journal of the American Medical Association, January 19, 1907.

Blood Cultures in Children.—T. M. Rotch and H. C. Low have been particularly impressed with the value of blood cultures in children in cases with indefinite and misleading histories, in their hospital service. In some obscure cases it may be the only means by which one can say whether sepsis is or is not present, and it may also reveal the etiological factor. They have found the method more practicable in children than has been supposed, though least so in the younger ones. In the first four years of life it was found possible to obtain sufficient blood for a culture in 21 per cent. of the cases tried, in the second four years 72 per cent., in the third 86 per cent. Their technique is described in detail: the blood is taken from a vein in the arm with all precautions against contamination, and directly inoculated into the culture medium. With this technique, they believe a negative culture is of value in prognosis, if not in diagnosis and treatment. The cases in which it promises to be of most help are the obscure conditions of so-called cryptogenic septicemia and autointoxication. The uncomplicated cases of endocarditis, chorea, arthritis and obscure septic infections offer a large field for its use.

Improved Technique in Otology.—W. S. Bryant reviews the improvements that have been made, but not yet incorporated generally into practice. These include: (1) The complete mastoid operation; (2) the improved instruments, such as electric burrs, Richard's curette, and the author's hand-driven front-bent gauge, which greatly increase the safety, speed, and facility of the operation; (3) rational disposal of the soft parts; (4) preservation of the sound-conducting mechanism in selected radical cases; (5) ligation of the jugular vein as high up as infection will allow before opening the sinus and exenteration of the jugular bulb; (6) management of brain abscess by the open method; (7) blood clot, drained blood clot, and the author's modification of the drained blood clot in the simple mastoid operation; (8) Reik's "protective sheet"; (9) blood clot in cases of epidural abscesses; (10) cosmetic results of the blood clot, drained blood clot, and evened-up bone wound; (11) lessened shock and jar; (12) shortened convalescence; (13) elimination of secondary operation; (14) avoidance of accumulated cicatricial tissue to interfere with the sound-conducting mechanism. All these measures, he thinks, tend to encourage earlier operations and favor better results than could be secured without them.

The Railroads and Tuberculosis.—J. R. Haynes advocates, as protection for the public, that purchasers of long-distance tickets should be questioned as to whether they have a cough, and if they have, that passage be refused, unless the applicant can show a certificate from the Board of Health or some reputable physician stating the cause of the cough, and that for those allowed to travel, special cars on specified trains should be provided. For consumptives traveling short distances cars with special nonupholstered compartments might be provided on certain trains. "Sentiment must be brushed away and tuberculous passengers must travel in such a manner as society may prescribe, in order that the many shall be protected." He would have it provided that any tuberculous passenger evading by false representations these provisions should, if discovered, be put in the hospital car, or if there be none, be put off at a station where he can be cared for and compelled to wait until the first hospital car going his

way arrives; and Haynes would have a heavy fine imposed on any physician who would connive at any evasion of these protective regulations. The hospital cars should be specially constructed and upholstered with leather or washable fittings, and carry a trained nurse and apparatus for disinfection. All compartments that have been occupied by the tuberculous should be thoroughly disinfected as soon as vacated.

The Sanatorium in the Tuberculosis Crusade.—C. L. Wheaton considers the sanatorium one of the most important aids in the crusade against tuberculosis; climate can no longer be considered the one great factor in the cure. The sanatorium has shown that pure air in any climate is the essential thing in the arrest of this disease. It is not, however, through the private sanatorium that the most beneficial results are to be obtained, there should also be public sanatoria for indigent consumptives, without depending altogether on antituberculosis associations taking the initiative and asking only for a certain amount of government aid. While a future successful serum treatment of the disease is a possibility, we should at present rely on the rational methods at our command and discourage the tendency to faith in nostrums and quacks.

Aerotherapy and Tuberculosis.—S. A. Knopf describes a window tent for the fresh-air treatment of the patients with tuberculosis, which is practically an awning put up inside of the window, instead of out of doors, to cover the patient's bed. By lowering or raising the window sash, sufficient air space can be left to ventilate the room also, without interfering with the open-air treatment, the air of the room not being allowed to mix with the air breathed by the patient. A transparent pane is made in the tent so as to enable the patient to be observed, without disturbing the arrangement. Knopf describes the advantages of the contrivance at length, its inconspicuousness, the shelter from room draughts, the opportunity for observation to patient, the prevention of drop infection by coughing, and chiefly its comparative inexpensiveness. The contrivance, though now obtainable from the manufacturers, the Kny-Scheerer Company, is not patented, and a similar arrangement can be improvised if necessary. In conclusion, he refers to the value of carefully conducted respiratory exercise and of solar therapy, in the treatment of consumptives

Painful Heel.—In defining this condition, J. J. Nutt says the term is not exactly descriptive or distinctive, as not all pain referred to the heel is due to the same condition. Young's definition, which is clear and exact, is "severe pain, accompanied by tenderness, in the center of the heel about the posterior attachment of the plantar fascia." It is probably not a rare condition, the milder cases are likely to be self-treated, and therefore do not come to the knowledge of the physician. Usually the only abnormality found on examination will be a limited range of flexion of the ankle; in other words, nondeforming club foot, or as he prefers to call it "Shaffer's disease" exists. He admits that other causes are possible; exostosis, bursitis, or neuroma may be the primary lesion, but he believes they are more often secondary to the traumatism to the plantar fascia. Nutt thinks that it is usually produced in those cases, in which the shortening of the gastrocnemius—the *sine qua non* in Shaffer's disease—exists to a slight extent, and that the plantar fascia, instead of becoming weakened and lengthening throughout its extent, has given way at the calcaneum attachment. This he does not find due to any sudden traumatism, but rather to the repeated slight strains of continuous stepping. The rational treatment is the relief of the strain on the shortened gastrocnemius by Shaffer's traction shoe with its steel arch, and by directions as to the proper method of walking.

The Lancet, January 5, 1907.

Pathology of the Liver in Cardiac Disease.—R. N. Salaman presents a paper based on the post-mortem records and detailed clinical histories of over sixty cases. He speaks of the ordinary case as the "back-pressure" liver, discussing the general "nutmeg" appearance, with its fat absorption through the hepatic lobule and its fresh fat deposition as the center. The main factor predisposing to the accumulation of fat in the central zone is undoubtedly stasis. The capsule is generally thickened, although this is slight in the case of Glisson's capsule. Fibrosis is found in varying degree about the sub- and central lobular and hepatic veins. His division of these livers is into three classes: first, the engorged liver; second, the nutmeg liver proper, and, third, the cirrhotic nutmeg liver. The author believes that the liver acts as a safety valve to the heart and that the various changes in structure undergone after prolonged back pressure modify that safety-valve action and seriously alter the clinical course of a given case. His experiments (detailed in the paper) show the following results: (1) that under conditions of cardiac stress the liver will draw off a large volume of blood from the right auricle; (2) that after a time certain changes take place leading to fibrosis which very materially affects the distensibility of the liver; (3) that the fibrotic process, by increasing the force of the liver's recoil, prevents the use of the latter as a reservoir in which blood may accumulate; (4) that in complete compensation there are no engorgement of the liver and no back pressure; and (5) that while the liver may be looked upon as a spongelike safety valve to the heart, continued use of this safety-valve action leads to its own abolition. The author then takes up the familiar clinical signs, such as superficial tenderness from extreme liver distention, tenderness of the liver on palpation, deep abdominal tenderness, onset of edema, etc., and claims that they bear out his theories. He divides the ascites of cardiac disease into (1) that of acute, and (2) that of chronic back pressure. The first type is characterized by the following features: (1) small in quantity, averaging one pint or in one exceptional case four pints; (2) it is of a high color and often bloodstained; (3) the peritoneum of the gut is opaque with engorged veins marked on it, or of its normal semitransparency, but with engorged veins, and (4) in all cases there will have been edema at the time of death, and in nine out of ten cases it will be of such amount as to be found post mortem. In this type meager ascites only appears after the utmost expansion of the liver has taken place, and this failing entirely to relieve congestion, the pressure has been transmitted through into the portal vein and its tributaries, some of the fluid coming from the intestinal peritoneum and some from the liver capsule. Ascites of the second type is characterized by: (1) being very large in amount, often requiring tapping; (2) of a clear yellow color; (3) the peritoneum of the intestines is invariably opaque and thick, peritoneal adhesions are very common (the veins may not be engorged to any great degree); and (4) the liver is invariably of the cirrhotic type. Ascites associated with this condition of liver is not necessarily the result of an increase in back pressure; it may and does often occur while the heart is compensated, so that some cases, notably one of the author's, spent the last year of his life being tapped and ended it with septic peritonitis, the heart being compensated the while. The effusion of fluid is in this type comparable to that in ordinary cirrhosis of liver, due to the difficulty experienced by the portal blood in making its way through the fibrosed organ, a difficulty that may be doubtless increased by some degree of back pressure.

Hyperplastic Tuberculous Pericolitis.—Three cases are reported by F. S. Kidd, who reviews the literature of the disease and gives a general description of it. The main points brought out are the following: first, that there arises a peculiar form of localized chronic hyperplastic inflammation in the submucous, muscular, and subserous coats of the bowel, which may lead to intestinal obstruction and its consequences, and which affects the mucous and serous layers to but a small extent. Secondly, that this is in all probability due to a localized infection of the wall of the gut with an attenuated form of the tubercle bacillus. Thirdly, that this form of inflammation is very liable to be mistaken for carcinoma or sarcoma either at operation or at necropsy. Fourthly, that by careful examination with the naked eye this form of disease can often be distinguished at the operation from a malignant growth, when once it is realized that such disease exists and the appearance it presents is borne in mind. Fifthly, that it can always be recognized with certainty by microscopical examination, which will prove of advantage in prognosis and treatment. Other features are that the thickening of the bowel consists of firm connective tissue and fat, affects the muscular, mucous, and subserous coats of the bowel, and rarely shows any "tubercles" or caseation. The ileocecal region is the most common site for this disease, but it is found at times in any part of the large bowel, especially the sigmoid flexure and rectum, and less commonly in the ileum. The mesenteric glands which drain the area of gut affected undergo a similar change or may present the usual picture of gland tuberculosis. In the rectum it has been mistaken for tertiary syphilitic thickening. A precisely similar hyperplasia caused by the tubercle bacillus occurs in other parts of the body, such as in the larynx, peritoneum, pleura, joints, and lymph nodes. The condition is not usually discovered until the peritoneal cavity is opened. Apart from excision, or after it, the treatment to be followed is that usually adopted for tuberculous lesions, perhaps combined with tuberculin injections. In one case the tumor was brought out on to the skin at the first operation, and was removed later. By this means all shock was avoided in the patient, who was in a condition of low vitality.

Bronchiectasis in Childhood with Some Observations on the Condition Known as Honeycomb Lung.—C. R. Box notes that the cavities in a so-called "honeycomb" lung may be of at least three different kinds. Some are bronchiolectases; some are atriectases combined with emphysema, and some are formed by necrosis of lung tissue. The frequency with which the bullæ project beneath the visceral pleura is in itself evidence that all are not simple bronchiolectases, for the bronchioles do not abut upon the serous membrane. The formation of a honeycomb lung is due to bronchopneumonia. Pleural adhesion plays no part in the initiation of the condition, although it may develop later, for in many cases there is no pleural adhesion at all. The question naturally arises whether these lungs are the antecedents of the chronic bronchiectases of childhood and later life. There is strong presumptive evidence that some at least of the cases do arise in this way. Comparison of a honeycomb lung with a saccular bronchiectasis from an adult makes it appear almost certain that the latter is but an advanced condition of the former. The shape, grouping, and communications of the cavities are similar, even the falciform septa may be recognized, but in the adult the walls and septa are thicker and the lining membrane more opaque in consequence of the long duration of the inflammatory process. Concerning treatment, the author notes that since most of the cases follow the bronchopneumonias of measles and pertussis, the indications are suggested by the features of these diseases. While the bronchiectases themselves represent permanent changes, much can be done to render the patient comfortable. The routine procedure should consist in regularly emptying the cavities as far as possible, and the administration of such drugs as are excreted by the lung and presumably exert an antiseptic influence on the bronchial tubes and their contents. The best method of emptying the cavities is by the process of inversion. Children can easily be taught to invert the body by leaning, face downwards, over the side of the bed with the hands resting on the floor. By this method considerable quantities of pus may be evacuated which would otherwise stagnate in the tubes and infect adjacent areas of lung. The best times to practise inversion are on rising in the morning, to get rid of the accumulated secretions of the night, and on retiring to bed, in order to avoid as far as possible overflow of the contents into adjacent bronchi and the irritating and disturbing cough excited by the presence of the pus. An alternative method of getting rid of the secretions is by the use of emetics, but in comparison with the method of inversion emetics are both uncomfortable and uncertain. The emetic usually advised is vinum ipecacuanhæ, and it is surprising what amounts of this preparation children will swallow without any result at all. The drugs which yield the best results in practice are garlic, creosote, turpentine, and cod-liver oil.

British Medical Journal, January 5, 1907.

Functional Albuminuria in Athletes.—W. Collier presents the results of his observations on Oxford University students in training for boat racing. Tests were made of the urine of 156 men. With the cold nitric acid test 49 showed no trace, 24 a slight ring, 54 a definite ring, and 27 a very thick ring; in other words, with this particular test 81 specimens out of 156 contained a very definite amount of albumin. With the heat and nitric acid test 24 showed no trace, 41 a faint trace, 58 a definite cloud, and 31 a thick cloud: that is, 89 out of 150 showed a very definite amount, or 57 per cent. of all the cases. The better the crew the more constantly did the albuminuria show itself. The author is aware of the incompleteness of his observations, for he says it would have been more satisfactory to have examined the men in the morning, before their rowing, and again in the afternoon, after it. He asks, ought we longer to advise young men who pass large quantities of albumin after severe muscular exertion to give up all hard athletic competition? He thinks not. It would appear that just as we may expect to get evidence of hypertrophy of the left ventricle and emphysema in the man who habitually indulges in violent athletic contests, so we may expect to find a definite amount of albumin in his urine for a few hours after violent exercise. Finally, he asks, ought the assurance companies to continue to refuse to consider the acceptance of the lives of young men between the ages of say 18 and 30, whose urines are found to contain albumin after exercise when it can be shown that no albumin is present after rest or after a meal? He thinks not.

Age Incidence of Gastric Ulcer in the Male and Female.—W. Calwell notes, regarding the age incidence in the female one fact of importance, namely, the sudden and profuse hemorrhage occasionally attacks the adolescent female who has made little or no complaint of stomach trouble; it is quite possible that this blood may come from an oozing, but in other cases it has been clearly demonstrated that it is from an ulcerated blood-vessel. The author regards it as very credible that small ulcers form and heal with great rapidity. Clinical histories would lead to the belief that they may break down in a few hours, and it can be understood how healing might occur in the same period of time if the edges of the ulcer could be kept in apposition, assuming that the pathological changes had ceased. The author presents a chart showing the age incidences in 200 cases, the time taken being that of the onset of symptoms. In many cases of hematemesis it may be possible that repeated bleeding may be brought about by alternating distention and contraction of the stomach, and that attention is to be paid to the extent of gastric resonance, and frequent sippings of a mild carminative tried as a treatment. Such cases are not rare, although a fatal termination is rare; but there is still the much larger class of cases, which resemble this case in their often slight, evanescent dyspepsia, and in their chlorotic condition, but do not complete the picture by an attack of hematemesis; they are mostly classified as "tea," "anemic," or "neurotic dyspeptics." The simplest explanation seems to be that many of these cases are really cases of ulcers, and that the accident of hematemesis depends on whether the ulcer is situated on a vessel or not, and the accident of perforation, which also occurs unexpectedly, on the depth of the ulcer. In such acute cases where, as happens in the very large majority, no complication occurs, recovery is rapid with rest and a little starvation. Each time, however, these attacks recur, the symptoms of chronic ulcer become more apparent. Nearly every one of these female patients is chlorotic, and if we pursue our investigations, nearly every chlorotic, in marked contradistinction to the adolescent male, has, or has had, some stomach trouble. The author's chart shows that ulcer in the female increases in frequency coincident with the increase of chlorosis. After the ages of 25-30 the onset of ulcer is about the same in the two sexes. The author declares that there is presumptive evidence that if we exclude all cases of ordinary gastric catarrh or dyspepsia from irritant food, and of dyspepsia of neurotic origin, we have still a large number of cases of "dyspepsia" in the adolescent female which are really due to ulcer; that these ulcers rapidly form and probably as rapidly heal, and that it is only by the accident of hemorrhage or of perforation, or of repeated relapses leading to chronicity that we recognize their real nature; and, lastly, that there are apparently two kinds of ulcer—one connected in some mysterious way with chlorosis and frequently with amenorrhea, probably being a developmental disease; and the other being a type which occurs pretty equally in both male and female, and is not often seen till after 20.

Pythogenic Pneumonia.—H. Freeth reports the case of a woman of 28 years with a severe catarrhal throat. The plumbing in the house in which she lived was not properly flushed. The day after she was first seen her husband came down with a lobar pneumonia, which ran a favorable course and defervesced on the ninth day. The wife's throat had meanwhile become well, and she nursed her husband, but on the ninth day after his defervescence she was attacked with pneumonia at the right base, and in about another week the left lung became involved, but she recovered without incident. The author notes the following points: (1) The almost simultaneous infection of the wife's throat and the husband's lung at a time when the house drains were dry and foul, favoring the opinion that the nature of the infection was the same in both (septic?), and fixing the incubation period of the pneumonia to within three days. (2) The infectiousness of the disease, as proved by the wife's attack, unless it be supposed that her system had been infected from her throat, and that the disease had developed later in the lung—a supposition, I think, rendered of little value by the fortnight of health she enjoyed between the two complaints. (3) The influence of insanitary conditions as a source of the infection, lending weight to the term "pythogenic pneumonia."

Filaria Among the Troops in Jamaica.—C. F. Wanhill presents the following conclusions: Although the majority of the dogs of the island are infected with *Filaria immitis*, human filariasis is comparatively unknown. Although, since the slave days, the disease must have been continually introduced into the island, there are some local factors which are against the successful development of the parasite in the human body. One factor may be the malarial poison, which must be present in most of the native population at some period of their lives. Dogs do not suffer from malaria, and their universal infection with filaria may be thus accounted for. The disease is so rare that no special precautions to permit its introduction among the British troops on the island have been thought necessary.—*Journal of the Royal Army Medical Corps.*

Book Reviews.

THE MEDICAL STUDENT'S MANUAL OF CHEMISTRY. By R. A. WITTHAUS, A.M., M.D., Professor of Chemistry, Physics, and Toxicology in Cornell University. Sixth Edition. New York: William Wood & Co., 1906.

IT is only four years since the fifth edition of this work appeared. On that occasion the section on chemical physics was enlarged and that on organic chemistry was rearranged and largely rewritten. At the same time a section on physiological chemistry, consisting of over one hundred pages, was added. In the present edition the section on chemical physics and general chemistry has been entirely rewritten and rearranged, and also considerably extended in scope. The section on inorganic chemistry is practically unchanged; and that on organic chemistry has been extended and rearranged where necessary. The section on physiological chemistry has been greatly enlarged and almost entirely rewritten; it is a subject of vast importance, and is here treated most admirably; and although the section occupies two hundred pages, it is difficult to see where condensation or elimination could have been effected. Indeed, the student will probably find that the matter here presented is already in a sufficiently concentrated form. The book has, for a long time, been well known as a first-class textbook; and those who have made acquaintane with the earlier editions can be assured that the present volume exceeds even the high standard attained by its predecessors. The book is literally full of chemistry; and if physicians expect to be able to understand present-day medical problems they must be well equipped in this branch of science. We know of no book which will give the physician as much solid information on this line as the volume before us. The arrangement of the subject is logical, the typography is excellent, and the book contains everything on chemistry that the student or practitioner is likely to require. At the same time the volume contains nothing extraneous or superfluous, and nothing that will have to be unlearned. In addition to its scientific value, the book has literary merits of a high order which go far toward making the study of the subject more attractive. To the physician in search of an up-to-date chemistry, which is adapted to his particular and peculiar needs, and is also authoritative and readable, and which is neither weighted down with academic discussions nor diluted with the facts, fancies, or fictions of pharmacy and therapeutics,—we would say, get this book, and study it.

THE PATHOLOGY OF THE EYE. By J. HERBERT PARSONS, B.S. D.Sc. (London), F.R.C.S. (England), Assistant Ophthalmic Surgeon, University College Hospital; Assistant Surgeon, Royal London (Moorfield) Ophthalmic Hospital; Ophthalmic Surgeon, Hospital for Sick Children, Great Ormond street. Volume III. General Pathology.—Part I. New York: G. P. Putnam's Sons, 1906.

THE third volume of "The Pathology of the Eye," by J. Herbert Parsons, contains 352 pages of text. It treats of the "general" pathology of the eye. The consideration of congenital abnormalities occupies 137 pages. The different parts of the eye are considered separately. A short bibliography, which in the rarer conditions covers all of the published cases, is found at the end of each article. The description and the known facts are given completely but briefly. The deductions drawn are logical and show evidence of a wide grasp of the subject and a rare discernment. The illustrations, which are in black and white, are sufficiently numerous, are well chosen, and properly supplement the text. A chapter is devoted to the pathology of myopia, one to hypermetropia and astigmatism, one to the normal circulation of the eye, including the arterial, venous, and lymphatic systems, and one to the nutrition of the eye, taking up the nutrition of the cornea, lens, and conjunctiva. The theory of immunity, normal intraocular pressure, and glaucoma receive a chapter each. This volume is one of much interest, the descriptions of congenital anomalies presenting rare conditions. The consideration of the circulation and nutritional conditions introduces questions that are of the greatest importance in the study of the morbid processes of the eye. This series of books is of exceptional worth to the ophthalmologist, and is also of value to the general pathologist.

PREVALENT DISEASES OF THE EYE. By SAMUEL THEOBALD, M.D., Clinical Professor of Ophthalmology and Otology, Johns Hopkins University. Philadelphia and London: W. B. Saunders Company, 1906.

THE matured experience of a well-informed, careful worker in ophthalmology is manifest in the pages of this excellent work. While the optical part of ophthalmology may be written, and well written, by one who has but recently completed the study of physiological optics, the clinical part cannot be well presented by any other than one who has had many years of practice with abundant material for observation. The volume before us is one of 551 pages. It is well printed and abundantly illustrated. Chapters on "Methods of Examination" and "General Observations Upon Treatment" are followed by chapters on "Diseases of the Eyelids and Orbit," "Diseases of the Lacrymal Apparatus," and diseases of other parts of the eye in natural sequence. A special chapter is devoted to glaucoma. Anomalies of refraction and anomalies of the muscles are then described. Then comes a chapter devoted to injuries of the eye and its appendages. An appendix devoted to formulæ and an index follow. The descriptions of the diseases of the eye are concise and up to date; facts with very little theory are set forth. The operations on the eye and adjacent tissues which have been proven to be of greatest value are described at considerable length and the technique is made sufficiently plain to enable any one possessing general surgical skill to perform them with promise of success. The work is an excellent one of its kind and may be read with profit by all who are doing practical work in ophthalmology.

AIDS TO GYNECOLOGY. By ALFRED S. GUBB, M.D. (Paris), M.R.C.S. (England), Late Senior Obstetric Physician, Westminster Hospital, etc. Fourth Edition, Tenth Thousand. New York: William Wood & Co., 1906.

As an outline for further study, or in the place of notes of lectures, this volume will serve a useful purpose. As a rule the salient features of each disease are presented in such a way that they may impress themselves upon the memory of the student. There are several tables of classification and of differential diagnosis, and illustrations are inserted where necessary.

BUFF. A Tale for the Thoughtful. By a Physiopath. Boston: Little, Brown & Co., 1906.

THIS is a farrago of nonsense, antivaccination rot, and tirades against scientific medicine, yet it contains some sound doctrine regarding diet, fresh air, and exercise. It will probably do a lot of harm to the ignorant, just as Christian Science does, but it contains some nuggets which might be of service to the physician who is too wedded to the materia medica and neglects the dictates of commonsense. But the man who is in such a parlous state is not likely to be converted by a book with so much error and so little sense as this.

SAUNDERS' POCKET MEDICAL FORMULARY. By WILLIAM M. POWELL, M.D., Author of "Essentials of Diseases of Children"; Member of Philadelphia Pathological Society. Containing 1,831 Formulas from the Best Known Authorities. With an Appendix Containing Posological Tables, Formulas, and Doses for Hypodermic Medication, Poisons and their Antidotes, Diameters of the Female Pelvis and Fetal Head, Obstetric Table, Diet Lists, Materials and Drugs used in Antiseptic Surgery, Treatment of Asphyxia from Drowning, Surgical Remembrancer, Tables of Incompatibles, Eruptive Fevers, etc., etc. Eighth Edition, Adapted to the New (1905) Pharmocopœia, Philadelphia and London: W. B. Saunders Company, 1906.

IT is a poor physician who has to resort to ready-made prescriptions in his treatment of disease, yet a formulary of this kind is not without its uses. Even the best of therapeutists sometimes fails to get the results he expected from the remedies provided, and he may in such a case find a hint in looking over the formulæ in this book which will put him on the right track. The diseases are arranged alphabetically, and under each are given a number of remedies and combinations of remedies which have been found serviceable in treatment. The book is interleaved with blank pages, upon which the possessor may record his "favorite prescriptions" and those which he has found of service in special cases. A thumb index facilitates ready reference. In addition to the formulæ there are a number of useful tables indicated in the title of the book.

BLAKISTON'S QUIZ COMPENDS. A Compend of Genito-urinary Diseases and Syphilis; Including Their Surgery and Treatment. By CHARLES S. HIRSCH, M.D., Assistant in the Genitourinary Surgical Department, Jefferson Medical College Hospital. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1906.

THIS is the latest addition to the well-known series of quiz compends, and it is up to the standard of the best volumes of the set. The book contains all that the student is likely to want on the subjects in question. The text is clear, concise, and readable; and the illustrations are well selected. In case another edition is called for, the publishers should have the ten pages of prescriptions, at the end of the volume, thoroughly overhauled. Chemical formulæ, English, and Latin (often incorrect) seem to be thrown together in haphazard fashion, and the result is a style of prescription writing which should be carefully shunned by students and authors alike.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, Held January 3, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Address of the Retiring President.—Dr. CHARLES L. DANA chose for the subject of his address "The Academy of Medicine," and said that the custom of having a retiring address was not a widely prevalent one, but that it was not an unwise one if the President retired without too much forensic effort, and used the opportunity chiefly to tell what his experience as an executive officer had suggested for guidance and inspiration. Bearing upon the latter, he said that the dominant feeling created in him by his two years association with this body was one of enthusiastic conviction that this Academy did extraordinarily important work for the profession and community, and had the capacity to do more. Few could realize how far-reaching and effective this organization had been. The management of so complex a body, with its thirteen constituent societies, its building, its books, involved no small amount of anxiety and responsibility. He confessed that after these years of rather strenuous attempt to bring out all that was possible in the Academy, there had come to him a real affection for what was technically only a soulless corporation. As he left the Presidency this was his feeling: That the Academy of Medicine was an organization wisely planned and unselfishly and effectively organized to bring out what was best in scientific and practical medicine in this community, and he said he could not finish his task without expressing his awakened enthusiasm in the Academy, knowing so well the work it did for professional progress and the betterment of the entire community. He was imbued with the Academy idea, and thought that all communities large enough to form a nucleus of physicians would be better off if the physicians organized on basic Academy principles. It was the Academy or its equivalent that humanized and elevated the medical profession. He did not mean to belittle the regular and necessary State and County organizations. We must have these, but must not stop with them. The doctor needed to have his social instincts properly satisfied. The change in the conditions which affected medical societies in their work was a matter which must seriously interest those who were responsible for their success. The demands upon the doctor's time made it necessary that a medical meeting should mean something to him, or he would not come to it. This had led to the appointing of a Council of the Academy, which met twice a year at least and formulated lines of work and subjects likely to be most interesting and important. It had to be taken into consideration that to a large extent clinical or descriptive medicine, and even gross pathology, was a finished story. The modern clinician had to work with the laboratory at his side in order to make progress in the knowledge of disease. There was still a field of prevention and therapeutics where much work remained to be done. It was true that we had not yet learned to interpret accurately what the patient said he felt. It was easy enough to recognize a crepitant râle or a cardiac dilatation, but not so easy to explain what was the matter when a patient said he had a persistent pain in the back, a continual pressure on the top of the head, or nervous indigestion, etc. Some, indeed many, doctors assumed that if nothing could be seen, heard, felt, or precipitated in a test tube, there was nothing the matter with the patient, whereas exactly the contrary was true. The exact interpretation of subjective complaints furnished a wide and perhaps the only wide field left, calling for original, careful, and acute clinical investigation. The annual reports had shown the prosperous condition of the Academy at the present time. Soon they would have a waiting list, although the limit of membership had been increased. Three new sections had been organized and had begun work. The attendance and interest in the sections had never been greater. Although it cost much money to run the Academy, yet its income paid its current expenses, and had allowed money to be put away this year in the sinking fund, and over $5,000 to be added to the library fund. There had been established a course of public lectures. Fresh interest was shown in the museum and historical department of the library. In closing, Dr. Dana said they needed the sum of $200,000 with which to enlarge the Academy and furnish room for the growing library. They also needed $200,000 as an endowment fund with which to publish a monthly bulletin of the work done.

Address of the Incoming President.—Dr. JOHN A. WYETH gave this inaugural address and spoke on "The Value of Organization in Medicine." He said that intelligent cooperation between individuals for the accomplishment of a given end had marked every step in human progress. Beginning with the organization of families into tribes, and these into States and nations, the more enlightened people of the earlier days became masters of the world about them. Scarcely a page in history failed to convey the lesson of the value of organization, but it was left to modern times, to a higher civilization, and chiefly to the profession of medicine, to apply the lesson to the amelioration of suffering and the saving of life. Toward the latter part of the eighteenth century and in the earlier years of 1800 there were signs of dissatisfaction with existing conditions in the profession, but there was really no great awakening until our own times. At the annual meeting of the Medical Society of the State of New York, in 1844, attention was strongly directed to the subject of medical education and the necessity of a higher standard of qualification, both preliminary and medical; at the meeting of this society in February, 1845, Dr. N. S. Davis, a delegate from Broome County, introduced a resolution, recommending a National Convention, to convene in the City of New York in May, 1846, for the purpose of adopting some concerted action towards elevating the standard of medical education in the United States. In 1846 the proposed organization of a national body took definite shape, and in 1847 the American Medical Association was organized. Among the definite subjects then stated were the following: (1) The standard of preliminary or preparatory education should be greatly elevated, or rather a standard should be fixed, for there was none then, either in theory or in practice. (2) They should elevate the business of private teaching to that position which its intrinsic importance demanded. (3) A more uniform standard of qualification should be required of the candidates for medical honors. (4) They should devise some mode to stimulate the ambition and arouse the energies of the profession to a higher state of intellectual activity and scientific inquiry. While this proposed organization of a national association was exciting much interest, a number of distinguished physicians in New York City, on November 18, 1846, met and proposed the foundation of the New York Academy of Medicine, and this organization was completed on January 13, 1847. From these dates the influence of these two bodies made itself felt in the profession. As far as the history of the medical profession in the United States was concerned, in his opinion the most important event occurred in 1900, when the American Medical Association appointed a committee on reorganization, which committee submitted its report at the annual meeting of the Association at St. Paul, in 1901. Dr. Wyeth then reviewed some of the difficult problems connected with this great undertaking, especially the differences which had divided some of the State societies into factions, and especially that which had prevailed in the Empire State. The real value of organization in medicine was in the influence they could bring directly to bear upon the body politic, and through this medium secure the legislation which would solve these serious problems,

and they could only do this by intelligent cooperation and by the sacrifice of much of their material interests to the public good. Organized medicine should take more note of politics than it had hitherto affected.

Reminiscences of Surgical Practice in New York During the Period of the Early History of the Academy.—Dr. Stephen Smith said that they could get a good idea of surgery as a science and an art in New York City in the middle of the last century by a study of the qualifications of the representative surgeons of that period, by the character of the teaching in the medical colleges, by the methods of practice in the hospitals, and the surgical literature. The three groups of representative surgeons were according to their ages, those over 50, Valentine Mott, J. Kearney Rogers, and Willard Parker; those over 40, Alfred C. Post, John Watson, and Guerdon Buck; those over 30, James R. Wood, John M. Carnochan, and William H. Van Buren. The first group represented the teaching and practice of the school of Hunter.

Valentine Mott owed his success to his aptitude, training, and opportunity. He gave extraordinary attention to order, detail, and cleanliness. He prepared for operation even of an unimportant character by the most painstaking dissections and review of the simplest details. He invariably cleaned his instruments before, as well as after an operation. His operative wounds rarely suppurated, which was the result sought by the school of Hunter, but never completely secured by other operators as by Mott. We now discover that his habits of personal cleanliness and attention to minute detail secured, in a large measure, asepsis. His pioneer work began with the ligature of the innominata in 1818. This was not only his greatest achievement in operative surgery, but the most brilliant operation ever undertaken by any surgeon up to that date. It was by no means suddenly conceived and executed as an emergency operation, but was the ripe fruit of years of study and preparation. They who knew him honored him for the breadth of his studies, his love of scientific truth in every department of research, his humanity as shown in his lecture on the condition of the tenement population, and his efforts to secure our present Health Department, his patriotism so conspicuous during the Civil War, and his devotion to the highest interests of his profession. J. Kearney Rogers' reputation rested upon a single operation of ligation of the left subclavian artery within the scaleni muscles, in 1845. This operation was only second to that of ligation of the innominata in the difficulties attending the dissection necessary to expose the artery. Sir Astley Cooper had attempted the operation and failed. In operating, Rogers was very dextrous and expeditious, two qualities most prominent in the preanesthetic period. Willard Parker was professor of surgery in the College of Physicians and Surgeons. He was not a scholar nor an investigator, but an intensely practical surgeon. His teaching was also practical rather than theoretical and speculative.

The second group of surgeons was different from the first. They were all connected with the New York Hospital, but none of them took special interest in operative surgery. Post's clinica were of interest chiefly because of his accuracy of statement in explaining the nature of disease. Buck was a laborious and painstaking practitioner, whose clinics were entirely wanting in everything like glamour. His success depended chiefly upon the extreme care of his patients. He would often awaken the house surgeon at the hospital at a late hour at night by a visit to a patient in a critical condition. Watson was generally regarded as the most scholarly surgeon of the entire series, his reputation resting on an address on the history of medicine in the early times.

The third group of surgeons found their opportunities at Bellevue Hospital. Wood's great service to the profession was the conversion of Bellevue from an almshouse into a modern, well organized hospital, and then making it a clinical school. His clinics were made attractive by the variety of operations performed, the brilliant display of instruments, and the frequent dramatic instances which occurred. Carnochan received his education at Edinburgh and London, and was a brilliant scholar, thoroughly equipped by nature and training for a great career, both as a teacher of the science and a practitioner of the art of surgery. He was acceptable in the former, and eminently successful in the latter. Van Buren was regarded as giving promise of a career second only to that of the senior Mott. He descended from a long line of eminent physicians, and no surgeon in the entire list combined so many qualities making for success, whether as a teacher or as a practitioner. He was more thoroughly familiar with the advanced opinion of surgeons than any other clinical lecturer, and his classes were always large and attentive.

In the medical schools of New York were found as professors of surgery, Willard Parker in the College of Physicians and Surgeons, and Samuel D. Gross in the University Medical College. Parker's lectures were almost wholly devoted to practical subjects, the principles of surgery being very briefly discussed. Scrofula was much dwelt upon as a dangerous complication in surgical diseases, but syphilis received only a passing notice. Gross, unlike Parker, was a student and investigator, and discussed broadly the principles of surgery as illustrated by the pathology of diseases, and hence, he gave less time to the details of practice.

The most accurate knowledge of the status of surgery at any time or place was gained from the viewpoint of the wards of the hospitals. The New York and Bellevue Hospitals were, in 1850, rival centers of surgical instruction and practice. They were very unlike in organization and management. The New York Hospital had been established on the basis of the London hospitals, and everything about it had the air of age and respectability. The practice of surgery was along conservative lines established by Wright, Post, Mott, and Stephens. In the wards the greatest interest was manifested in fractures. Compound fractures of the leg were treated in boxes partially filled with bran, as an absorbent of the abundant flow of pus. Fractures of the thigh and its neck were treated with the long side splint, extension and counterextension being made from its extremities by straps and bandages which created such excoriations as greatly to impair its usefulness. Ligation of arteries, trephining for fractures of the skull, excision of bones were major operations. At Bellevue many of the vices of the almshouse still persisted, and the service was largely confined to chronic diseases. Abscesses, ulcers, caries, syphilis in every form and stage, and similar pus-generating affections filled the wards. There was pus everywhere. Healing of wounds by first intention was unthinkable. Amputation was the favorite operation, and the clinics were most brilliant and spectacular affairs.

Looking backward from the viewpoint of half a century the surgeons of 1850 appeared like men of heroic mould, and their achievements, under conditions almost absolutely prohibitive of success, even more marvelous than the remarkable deeds of to-day.

Reminiscences of Medical Practice in New York During the Period of the Early History of the Academy.—Dr. A. Jacobi read this paper (see page 129)

Fracture of the Clavicle.—It is frequently difficult especially in children, to secure adequate fixation of the fractured bone by any of the ordinary methods. Cordua says that in many instances good results may be obtained by putting the arm of the injured side behind the back in such a position that the finger tips touch the angle of the opposite scapula. It is not necessary, in most cases, to continue this form of dressing longer than the first few days, and it should not be kept up any longer than is required, as the patient is thereby prevented from sleeping either on his back or on the injured side.—*Zentralblatt für Chirurgie.*

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Held at Baltimore, Md., December 11, 12, and 13, 1906.

THE PRESIDENT, DR CHARLES H. NOBLE OF ATLANTA, GA., IN THE CHAIR.

(*Concluded from p. 122.*)

Puerperal Thrombophlebitis of the Pelvic Veins.—This was the title of the President's address, delivered by Dr. George H. Noble of Atlanta, Ga. Attention was directed to the surgical aspects of this question. Of the 32 cases of puerperal sepsis collected the infection was divided as follows, with reference to location: Metrophlebitis, 11; metrolymphangitis, 4; abscess in parametrium, 8; thrombophlebitis (suppurating) of broad ligament, 2; suppurative peritonitis, 7; and deep laceration of vagina, 7. Thus of the entire number there were thirteen cases of pelvic phlebitis, two of which were in the large veins of the pelvis. If thrombosis of the pelvic veins occurred in 6 or 7 per cent. of puerperal infection, the mortality being high, the author thought considerable saving of life might be brought about by early recognition of the disease and prompt interference. He thought the showing should be greater, for the number of cases coming under his observation did not correspond with the percentage given in the above list. Thrombosis might begin early, but usually the symptoms were not clearly defined until late in the puerperal state, making a distinction between it and other clinical manifestations of sepsis, excepting intramural abscess of the uterus. But exceptionally the symptoms might appear earlier. In one case the chill came on on the third day, and on the ninth the thrombus had advanced to such an extent that resection of the left side of the uterus and of the corresponding broad ligament was acquired. The disease was often complicated with other septic conditions, such as involvement of the tubes, ovaries, suppuration in the parenchyma of the uterus, parauterine tissues, or the clot itself might be permeated with pus, the latter escaping directly into the circulation. In differentiating between thrombosis and intramural abscess of the uterus, uncomplicated by peritonitis and adhesions, small, rounded, flat elevations on the surface of the uterus might be felt in patients with very thin or relaxed abdominal walls. Such cases presented the ordinary septic pulse and temperature curves, and did not have the distinct interval of nonsuppurating thrombus. When complicated by adhesions, or diseases of the appendages with tense abdominal walls, exclusion of intramural abscess, and detection of tortuous veins, were extremely difficult. Suppurating thrombosis very likely might be overlooked when complicated with peritonitis, pus tubes, etc., unless the symptoms of pyemia supervened, or the pulse showed a tendency to become climbing in character. These were suggestive of the true condition. Any puerperal case with pelvic lesions, variable temperature, and climbing pulse of three to four weeks' duration, without signs of improvement, justified an operation of some kind, especially if the uterus proved negative as the source of trouble. If a mistake was made in diagnosis, and the location of the infection was found in the Fallopian tubes or abscesses in other parts of the pelvis, no surgical error was committed, for they too were in need of serious attention. There were several plans of procedure. First, excision of the thrombosed veins; second, ligation of the thrombosed veins; third, hysterectomy. In addition to these, attention should be given to the complicating conditions. One author objected to excision on account of the liability of reinfecting the wound by soiling the parts with the clots. In two of the author's cases in which the veins were lacerated by digging the clots out of the broad ligament with the fingers, the temperature range for two or three days was quite irregular and reached high marks at short intervals (103°-105°), but some of this temperature might have been due to the extensive surface involved. Each of these had numerous abscesses in the uterus, ovaries, and pus collections between the coils of the intestines; besides, the omentum and intestines were softened and adherent from the umbilicus down. As the chill was not repeated in either case, it was likely that soiling the wound with clots had little to do with it. The number of cases in which excision had been resorted to was too small to draw accurate conclusions. Ligation of the veins was not satisfactory, especially if the clots became infected with pyogenic cocci. Hysterectomy was extremely dangerous in this condition. In the first place, it was often delayed too long to remove successfully all the infected centers. When thrombosed vessels were confined to the uterus, there were some chances of success, but propagation through the vessels into the broad ligament extended the infected field into the pelvic veins, and at times the uterus might not be at fault, for the thrombi might lie exclusively in vessels outside of that organ. Removal of the uterus under such circumstances was worse than useless, as it would leave the thrombosed vessels undisturbed. On the other hand, excision of the diseased veins without hysterectomy was promising except in extreme cases. In the summary of the small number of cases accessible, the results were as follows: Resection of vein, a mortality of 28 4-7 per cent.; ligation of veins, 44 4-9 per cent.; hysterectomy, 64 1-4 per cent. He ventured the assertion that until further experience shall have worked out the solution of this problem, the opinion must be accepted that early recognition of septic thrombosis of the pelvic veins, followed by prompt excision, was the best method of relief we could offer our patients in this disease.

Surgical Treatment of Tuberculosis of the Kidney.—Dr. HOWARD A. KELLY of Baltimore reported a surgically-treated series of sixty-two cases of kidney tuberculosis from the gynecological clinic at the Johns Hopkins Hospital and from his private sanatorium. This list embraced fifty-seven nephrectomies—including simple nephrectomy, and those combined with removal of the ureters, and in a few cases also parts of the bladder—four nephrotomies, and one partial nephrectomy. The extreme rarity of a spontaneous healing, even by a complete destruction of the kidney and occlusion of its ureter, was emphasized. The author in a large experience had never met with this condition, which agreed with the statements of most others who had extensively observed the disease. With the rare exception of a kidney so sequestrated, the disease in all cases sooner or later involved the bladder, and from that led to death, either by infecting the sound kidney, or by extensively metastasing to other parts of the body. Of the operative procedures considered, nephrectomy must be regarded as merely a palliative measure to be employed in pyonephrosis cases. When the second kidney was sound, it was preliminary to a subsequent nephrectomy; when the sound kidney was diseased, it relieved suffering, and to some extent prolonged life. In the four cases in which it was the sole operation, the second kidney was involved, and all of these patients died within a year. Of the seven cases in which it was performed as a preliminary operation, and nephrectomy done later, all had recovered and were cured. Partial nephrectomy was indicated in cases where both kidneys were involved by tuberculosis, and both were secreting about equal amounts of urine. In the one case, where the author employed it, the patient died eight months after operation. A study of the specimens obtained by nephrectomy showed that in five kidneys the disease was localized to one pole, and that a partial nephrectomy sometimes offered the hope of eradicating the disease. Tuberculosis involving one-half of a horseshoe-shaped kidney presented another condition where partial nephrectomy was positively indicated. Nephrectomy was the operation of choice, and it should be employed first under all circumstances if the second kidney was sound; second, even when the second kidney was diseased, if the kidney to be removed was not functioning or only slightly functioning, and the other but slightly involved. The presence of albumin

and casts in the urine from the kidney not tuberculous was not a contraindication to operations. They usually disappeared after the removal of the tuberculous kidney, as was shown in four of the five cases. In the fifth case they persisted, and demonstrated a genuine nephritis, but this patient was actively engaged in teaching school seven years after her operation. Infection of the second kidney by the ordinary pyogenic organisms was not a contraindication to a nephrectomy, as was shown by three cases of the series. One of these was living, thirteen years after operation, another seven years, and another four years. Involvement of the bladder, far from being a contraindication to operation, was a most urgent indication, as bladder tuberculosis was not healable in the presence of a tubercular kidney above, whereas it did heal under proper treatment after nephrectomy. Coexistent involvement of the genital organs was not a contraindication. The author's experience in this class of cases was confined to women; five such cases were treated; three were permanently cured; one had only been recently operated on, and one died from the operation. Tuberculous genitalia must be removed as well as the kidney. This same complication in men, as shown by Rovsing's report of ten cases cured, could not be held as a contraindication to the operation. The presence of tuberculosis in the lungs, glands, joints, bones, and elsewhere, provided it was not very active, was no contraindication to the operation. Out of eighteen such cases treated by nephrectomy, and subsequent general treatment, thirteen were permanently cured from periods of two to ten years, and two had only been recently done. As tuberculosis of the kidney once started destroyed the kidney, and as the cases became more unfavorable after bladder involvement, a nephrectomy should be done just as soon as the diagnosis was made. The importance of this early operation was shown by the results in the twenty-one cases treated comparatively early in the course of the disease, *i.e.* with no bladder involvement, or only slight involvement around the ureteral orifice of the affected side. There had not been a death in this group, and all had been cured. Contrasting with this thirty-six cases with extensive bladder involvement, there were four primary, and within four years five secondary deaths, making a total mortality rate of 25 per cent. By reason of the fact that some of the author's cases were private patients, it had been possible for him to follow them all after operations. These observations after operation did not consist only of the reports of the patients, but also of careful urinary examination. The statistics from the nephrectomies were: Fifty-seven cases, 4 primary deaths, or 7 per cent. mortality; a total of 7 deaths within six months, 12.2 per cent. mortality; and a total number of deaths of 9, 16 per cent. mortality. Excluding from the series nine cases with residual bladder trouble still present, all of which except one had been operated on within a year and a half, there remained forty-eight cases, with thirty-nine complete cures, and nine deaths, a cure rate of 76.93 per cent. It was only by a knowledge of the frequency of such permanent cures that a just estimation of the operation could be arrived at, since the vesical irritability, owing to involvement of the bladder and other disagreeable symptoms, might be as great after the operation as before, unless a cure was obtained. As to the method of operating, when it was possible to do so without adding to the dangers of the operation, the ureter should be removed with the kidney, as by this means it had been found that the incision healed more promptly and the bladder tuberculosis, if present, was more amenable to treatment. In view of the remarkable results of surgical treatment, and the hopelessness of all medicinal measures, tuberculosis of the kidney more positively indicated operation than did acute appendicitis, and the realization of this fact by the profession, with the consequent possibility of early operations, would lead to better and better results.

Tuberculosis of the Kidney.—Dr. CHARLES P. NOBLE of Philadelphia reported ten nephrectomies for tuberculosis, nine of the patients being women and one a man. In each of the ten cases the tuberculosis of the kidney was primary, but in the man the lungs were also involved. This case ended fatally six weeks after nephrectomy in the natural course of the disease. The nine women not only recovered from the operation, but were restored to health. Three of them suffered from permanent loss of capacity in the bladder, due to the healing of extensive ulcers. In most of the cases the complicating cystitis and ulceration underwent a spontaneous cure after the nephrectomy. The following points were emphasized: No evidence of ascending tuberculous infection had come under the writer's notice. In each of the cases the tuberculosis of the kidney was primary, and the bladder, when involved, was infected by pus discharged through the ureter. The results of early nephrectomy for tuberculosis of the kidney were very satisfactory. The profession should be educated to appreciate these facts and to diagnose tuberculosis of the kidney at an early stage, before extensive involvement of the bladder or general dissemination of the disease had occurred.

A Study of Vaginal Cesarean Section With Especial Reference to Subsequent Pregnancy and Labor.—Dr. JOHN F. MORAN of Washington, D. C., after referring to the literature of this subject, stated that at the last meeting of the association he reported two cases of vaginal cesarean section, performed for eclampsia, both successful, and he now reported a subsequent pregnancy and labor occurring in one of them. He said it could not be denied that complications and sequelæ attended vaginal cesarean section, but that was also true of all the methods of accouchement forcé. Each had its value, and should be employed only after a thorough examination had determined its suitability. An exact knowledge of the condition of the cervix before acting was the essential prerequisite to success. The bougie, tampon, and metreurysis might be used when the cervix was undilated, provided time was not a necessary factor. Manual and instrumental methods should be applied only when the internal os was effaced or effacing. If applied while the cervix was intact they acted by divulsion, rather than by dilatation, with its consequent dangers of hemorrhage, laceration, and infection. It was in the latter class that vaginal cesarean section was particularly indicated, and, further, had the advantage that in case of urgency the uterus could be emptied at any period during pregnancy or labor in a given time. It was therefore a meritorious operation, and a valuable addition to our obstetrical resources.

Dystocia Following Fixation and and Suspension of the Retroflexed Uterus.—Dr. J. WHITRIDGE WILLIAMS of Baltimore, in a paper on this subject, reported four cases in his own experience, and collected thirty-four from the literature, in which cesarean section had to be done following some method of fixation for suspension of the uterus.

Dr. HENRY O. MARCY of Boston gave a brief sketch of one of Baltimore's greatest men—Dr. Horatio Gates Jameson, whose greatest contribution to surgery, he said, was the occlusion of arteries by buried animal ligature.

Hodgkin's Disease; A Type of Sarcoma.—Dr. WM. B. COLEY of New York referred to the fact that at present both pathologists and clinicians were widely at variance as to what constituted Hodgkin's disease. The theory that Hodgkin's disease was a form of tuberculosis, strongly advocated a few years ago by Sternberg and others, had been practically disproved by the work of Dorothy Reed. The theory which at the present time received the greatest support both by pathologists and clinicians was that Hodgkin's disease was a separate entity in the nature of an infectious process. This was the position held by Reed and the majority of recent writers. The only other theory that had received much consideration was that Hodgkin's disease was in the nature of a malignant tumor, or a variety of sarcoma. While this was the view originally held

by Virchow, who called it lymphosarcoma, and Billroth, malignant lymphoma, the same had been practically abandoned by later writers, and only recently had again begun to receive serious consideration. In favor of the infectious theory of the origin of the disease, Reed cited the facts: (1) That fever was frequently associated with Hodgkin's disease; (2) that the frequency with which the disease started in the cervical region suggested the possibility of infection gaining entrance through the mucous membrane of the mouth; (3) the absence of capsular infiltration and implication of adjacent structures; (4) the peculiar giant cells found in the tumors. Finally, and most important of all, the fact that metastases occurred only in preexisting lymphoid tissue. Dr. Coley, who strongly believed in the malignant nature of Hodgkin's disease, in answer to these objections, stated that his observation had been that fever was not an infrequent occurrence in malignant disease; especially in sarcoma if generalization had taken place. As to the neck being the frequent starting-point of Hodgkin's disease suggesting the possibility of infection, he stated that the same reasoning would apply to cases of sarcoma of the neck, which bore such a large proportion to the total number of cases. Coley had observed seventy cases of sarcoma of the neck in a total of 615 cases. As to the absence of capsular infiltration, this was by no means a universal characteristic of the tumors of Hodgkin's disease, as shown by the recent and very valuable contribution of Gibbon of San Francisco, whose report covered nine cases. His cases showed marked evidence of capsular infiltration and also answered a more important objection: that metastasis occurred only in preexisting lymphoid tissue. In some of Gibbon's cases metastases occurred where there was no possibility of the presence of lymphoid tissue and not only infiltrated the capsule but the surrounding structures, even the periosteum and bone. As another reason for regarding the process of the nature of a sarcoma, Coley cited several cases in which the clinical diagnosis was sarcoma, while the pathological report read Hodgkin's disease. Cases of Hodgkin's disease pursued a clinical course identical with that of sarcoma, infiltrating the surrounding tissue and causing death in precisely the same way. The recent work of Banti went far toward proving that not only Hodgkin's disease but also leukemia, both lymphatic and myelogenous, were really forms of sarcomatosis. Coley's conclusions, based upon a study of upward of six hundred cases of sarcoma, of which seventy originated in the lymph glands of the neck, are that Hodgkin's disease was merely a special variety of sarcoma, representing a fairly definite clinical and pathological type, but in many cases shading off into other types that corresponded most closely with that of an ordinary round-celled sarcoma. The evidence brought forward by Reed and others in favor of the infectious origin of Hodgkin's disease need not be disproved. Most of it held true in the case of sarcoma, and all of it but added to the slowly-accumulating mass of evidence in favor of the infectious or microparasitic nature of sarcoma, a conviction which the writer had long held.

The Surgical Aspects of Gastric Carcinoma.—Dr. JOHN B. DEAVER of Philadelphia said that from twenty-five to forty per cent. of all cancers of the body were primary in the stomach. Bryant, quoted by Van Valzah and Nisbet, showed that in Baltimore there were 200 deaths annually from cancer; Boston, 300; Philadelphia, nearly 500; New York City, nearly 900. Of these, perhaps almost one-half were directly due to cancer of the stomach. Chronic gastric dyspepsia was the chief predisposing cause of cancer. Cancer of the stomach presented clinically two forms. In one, a patient past middle life, without having suffered previously from indigestion, suddenly lost appetite, especially for meats, grew progressively weaker, more emaciated, developed epigastric pain, possibly a palpable mass; became subject to vomiting spells; vomiting a mass of foul-smelling and fermented coffee-ground material, and quickly developed cancerous cachexia. This was the classical picture of gastric carcinoma. The second and much larger class was composed of patients who had been lifelong sufferers from dyspepsia. Usually there were no definite symptoms, the patient having been treated for chronic gastritis. Patients who presented symptoms of gastric indigestion, which would not yield in a few weeks to medical treatment, should be subjected to operation. Timely resort to gastroenterostomy would save many patients from the development of gastric carcinoma. Until operation was more frequently undertaken in the very early stages of gastric carcinoma, gastroenterostomy must still be the operation most often adopted. It was rare in the author's experience for a patient in whom cancer had been certainly diagnosed before operation, to present conditions admitting of gastrectomy. A palpable tumor felt before operation would naturally suggest cancer, yet these tumors had been known to disappear after a gastroenterostomy; therefore, all palpable tumors were not carcinomatous in nature; and it was in this class of patients that exploratory laparotomy found its most legitimate field. Total gastrectomy must remain an operation of the utmost rarity. Personally, he did not approve of it. Subtotal gastrectomy was, in his opinion, as extensive an operation as it was wise to adopt. To sum up: By timely operation for the various causes of persistent indigestion, many a patient would be saved from developing gastric carcinoma. Early diagnosis of gastric carcinoma being so extremely difficult, and radical removal being only highly promising when an early diagnosis had been made, partial gastrectomy should be an operation limited to cases of malignant disease operated on for symptoms of pyloric obstruction or other gastric affections supposedly benign, in which the existence of cancer, though perhaps suspected, could not be certainly diagnosed before operation. Partial gastrectomy was the preferable treatment for these cases. In cases moderately far advanced gastroenterostomy should be preferred. Where the indication was to prevent starvation, jejunostomy was to be performed.

Vaginal Section as an Operation of Choice.—Dr. HENRY T. BYFORD of Chicago called attention to the fact that whereas vaginal section became quite popular among gynecologists a few years ago on account of its low mortality, the improved technique of abdominal section soon brought the latter into favor again and relegated the former to a comparatively limited field of usefulness. The cases adapted to vaginal section were mostly those in which the parts affected were more accessible from below, namely, those connected with prolapse and retroversion of the uterus, with prolapse of the ovaries, or with adhesions low down in the pelvic cavity, and cases of hysterectomy or myomectomy for small fibroids as well as hysterectomy for other small neoplasms and malignant diseases of the uterus. When the uterus was not to be removed the author preferred the incision posterior to the cervix for those cases in which the uterus was retroverted or readily retrovertible, and the cervix could be drawn well down near the vulva. The anterior incision had the advantage of enabling the operator to deliver the fundus into the vaginal entrance and also to draw the ovaries and round ligaments forward within easy reach. Among the disadvantages of the latter were a complicated wound which could not always be as satisfactorily sutured as the posterior incision, and the presence of the fundus in the vagina to interfere with manipulations, etc. When there were special reasons for avoiding abdominal section, the field of vaginal section might be extended by removing the uterus or if it be desirable to preserve the uterus by lateral colpotomy in connection with the anterior or posterior incision, or both. By ligating and severing the uterine artery, or by skirting or shaving the edge of the cervix with scissors or a sponge, and separating the broad and sacrouterine ligaments from the cervix, space could be obtained for the introduction of the whole hand into the

peritoneal cavity and for the employment of intraperitoneal illumination. The author had even extended the incision completely around the cervix, as for vaginal hysterectomy, separating the bases of both broad ligaments as well as of the sacrouterine ligaments and bladder, and afterward suturing the parts back to their original relationship without any bad results. Through the opening thus made the torn or perforated rectum could be successfully sutured. The author believed that while the utility of vaginal section would diminish with the perfection of the technique of abdominal section for pelvic conditions, there would always be a place for it, and the time had not yet come when a special training in gynecological surgery could be considered as superfluous.

Dr. JOHN C. MUNRO of Boston reported an unsuccessful case of aneurysmorrhaphy for abdominal aneurysm.

Appendicitis in the Negro.—Dr. HUBERT A. ROYSTER of Raleigh, N. C., said that in order to obtain some information on this subject he wrote to several surgeons practising in southern cities having a large proportion of negro inhabitants; the replies were unanimous in regard to the rarity of the disease in this race. During the ten years in which the author had practised he had removed the diseased appendix from negro patients fifty-four times. In forty of the cases a pathological appendix was found while operating for other conditions, such as pus tubes, fibroids, etc. Besides a few of these which contained pus, over one-half of the others were filled with fecal matter, usually soft. Practically none of these cases presented a definite history of appendicitis, but only that of the original lesion. Fourteen cases of primary appendicitis in the negro were operated on, three in the first seven and a half years, and eleven in the past two and a half years. During the latter period, two and a half years, the total number of appendix operations on both whites and negroes was 123, giving a relative frequency of practically 9 per cent in the colored race.

Injuries and Diseases of the Hyoid Bone.—Dr. RANDOLPH WINSLOW of Baltimore reported six cases, one that had come under his own observation and in his practice, and five from the literature. He said that tumors of the hyoid bone were both malignant and innocent in about equal proportion, and both required thorough removal with as much of the contiguous tissue as might be necessary. An early operation was as much to be desired in neoplasms of this bone as in those occurring in other parts of the body. The author's case was one of sarcoma of the hyoid bone and larynx. He excised the tumor of the hyoid and base of the tongue, larynx, and part of the pharynx under local anesthesia. The patient recovered from the operation, but died two months later from metastasis. The patient was a man forty-five years of age, who entered the hospital on January 9, 1906, suffering from dyspnea due to a growth in the region of the hyoid bone on the left side, which obstructed the larynx. Thirteen years ago a lump was removed from the hyoid bone and the side of the larynx, and patient was discharged cured in six days. It began to recur in three years, and had been in existence for ten years and slowly increasing in size. The voice was altered; there was dyspnea with stridor, cough, dysphagia; pulse rapid and weak. There was a lump found in the region of the hyoid bone projecting more to the left than to the right side; it was globular, and as large as a goose egg, hard and movable, but not painful. A skiagraph failed to show the hyoid bone, but a shadow of a growth was seen between the jaw and the larynx. On January 11 tracheotomy under cocaine was done to relieve the urgent dyspnea. Patient improved somewhat and desired a removal of the growth. It was thought inadvisable to administer an anesthetic; hence morphine-scopolamine was injected hypodermically and the skin infiltrated with Schleich's solution. Operation on February 1, 1906. Hyoid bone, base of tongue, whole larynx, and part of pharynx were excised without difficulty whilst the patient was conscious. The trachea was attached to the skin at the lower part of the neck and a large tracheal tube introduced; pharynx and skin sutured. There was no shock. At first the patient was fed through a large, soft catheter passed from the mouth into the esophagus; but later the pharynx opened and a tube was passed from the neck into the esophagus. Patient did well and soon sat up and was able to walk about the ward; but recurrence occurred in the neck, and he gradually failed and died in eight weeks. An autopsy showed extensive metastasis in the lungs, bronchial glands, liver, and mesenteric glands, whilst the microscopic examination of the growth showed it to be a round-celled sarcoma.

The following papers were also read: "Conservative Method of Managing Undescended Testicle," by Dr. Joseph Price of Philadelphia; "Gallstones without Symptoms and Symptoms without Gallstones," by Dr. Maurice H. Richardson of Boston; "Two Simple Surgical Tricks Worth Knowing, with Instruments Used," by Dr. Ap Morgan Bance of Louisville, Ky.; "Report of a Case of Ruptured Ovarian Tumor with Complications," by Dr. Rufus B. Hall of Cincinnati; "Hodgkin's Disease—A Type of Sarcoma," by Dr. William B. Coley of New York City; "Cysts of the Omentum," by Dr. R. E. Fort, of Nashville; "Some Disjointed Observations upon Our Technique," by Dr. A. Morgan Cartledge, Louisville; "Influence of Respiration upon Development of the Chest Deformity in Scoliosis, with Its Relation to Application of Plaster Jacket," by Dr. Michael Hoke of Atlanta; "Some Suggestions in Regard to the Surgical Treatment of Empyema," by Dr. Samuel Lloyd of New York; "Normal Involution of the Appendix," by Dr. Robert T. Morris of New York; "Splenectomy, Indications, and Results: Report of Five Successful Cases," by Dr. W. P. Carr of Washington, D. C.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Howard A. Kelly of Baltimore, Md.; *Vice-Presidents*, Dr. R. E. Fort of Nashville, Tenn., and Dr. Hubert A. Royster of Raleigh, N. C.; *Secretary*, Dr. W. D. Haggard of Nashville, Tenn., reelected; *Treasurer*, Dr. Charles M. Rosser of Dallas, Tex., reelected.

New Orleans, La., was selected as the place for holding the next meeting; time, second Tuesday in November, 1907.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held December 17, 1906.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

A Modification of the Obstetric Forceps, Eliminating the Danger of Excessive Compression.—Dr. A. ERNEST GALLANT read this paper, in which he described a safety lock on the obstetric forceps for the prevention of dangerous compression of the fetal head. After a brief historical review of the development of the obstetric forceps since 1733, Dr. Gallant demonstrated that the great danger of the so-called English lock lay in the fact that after the forceps were locked and traction applied the lateral pressure exerted by the uterine and vaginal walls on the convex surface of the blades forced them together to a degree which was highly dangerous to the fetal head, especially at those portions within the grasp of the tips of the blades, and frequently caused depression, fracture, and intracranial hemorrhage. The speaker presented two devices for avoiding this otherwise uncontrollable pressure: On the long-shanked forceps, by placing a "shoulder" at the junction of the shank with the blade of the left forceps, which prevented them from overlapping, and the blades from coming together any closer than it was originally designed that they should. For the same purpose, on the forceps made with the Chapman or loose lock, as was usually found on the Elliott forceps, he had combined

the English with the French locks, the thumb-screw of the latter being inserted, free, through a hole in the flange of the left blade, and screwed into the main portion of the shank. The right blade was provided with a notch on its inner side, partially countersunk, which embraced the thumb-screw, and when that was screwed home it fastened the blades together as in the Hodges forceps, and in that way maintained the fulcrum at the lock and prevented compression of the head. With this combination lock it was claimed that we could secure the head from injury and have all the advantages of the loose lock, the button lock, the set-screw lock, and at the same time bring into play Elliott's pivot at the extremity of the handles for holding the blades as widely apart as was deemed advisable.

Immediate Repair of the Soft Parts after Labor.—Dr. Henry C. Coe introduced his paper with the remark that the subject was so trite that it was impossible to do more than to emphasize anew old, familiar teaching. There could be little room for difference of opinion among obstetricians as to the advisability of repairing lesions of the soft parts after labor, but writers by no means agreed as to the best time at which the operation should be performed, nor did they all adopt the same technique. In discussing the subject, therefore, Dr. Coe said he would limit himself to his own experience. Immediate repair of laceration of the cervix was still a mooted question. In the presence of arterial hemorrhage there could be no doubt that it should be at once controlled by the passage of deep sutures. He did not believe it was necessary to repair every lacerated cervix at the time, but it was now his custom in every case of difficult delivery (high forceps or extraction) to be prepared to suture at once the extensive bilateral tear which was to be expected. With the present aseptic technique primary union was to be looked for, nor was drainage from the uterus interfered with if the operation was properly performed. It was exceedingly simple. The speaker said he preferred to operate as soon as the placenta was delivered, and not to wait until several hours, or even days afterwards, as some writers advised. Of course, there were cases in which the conditions would render it inadvisable to add even a few minutes to the anesthesia. Lack of assistance, bad light, and other complications incident to private practice might also prevent the accoucheur from repairing a torn cervix, excepting as a life-saving measure. But in the class of cases in which extensive tears were apt to occur no one should attempt a difficult obstetric operation without the assistance of a colleague. With regard to lacerations of the vagina, the speaker said he wished to emphasize the fact that their extent was often not fully realized until the parts were thoroughly exposed with a speculum and retractors. This applied especially to occipitoposterior cases in which the head was rotated with the forceps. Not only were deep and ugly rents produced by the most skillful hands, but they were too often only partly sutured, with the result that healing by granulation took place, and the production of extensive cicatrices. It was important not only to expose the entire length of the tear, but to keep the field of operation clear by placing a tampon against the cervix. One must not neglect to examine the anterior, as well as the posterior wall, for many lesions of the former were overlooked. Dr. Coe said he had nothing to add to his paper on "Immediate Repair of Injuries of the Pelvic Floor," printed in the *Transactions of the American Gynecological Society*, Vol. 29, page 219, and would only reiterate his opinion that it paid to do the work thoroughly, having ever in mind that the object of the operator was not merely to suture raw surfaces, but to go deeper and to pick up the torn fascia and muscles outside of the vaginal tube. It was now a truism that the submucous lacerations of both the anterior and posterior vaginal walls were of far more importance than the visible superficial lacerations. He believed that the time had come when, even in the absence of the latter, the careful accoucheur would seek to prevent subsequent cystocele and rectocele, and prolapsus by performing at once the operations usually done months later to correct these conditions, provided always that the patient's condition was such as permitted one to spend an additional quarter of an hour in the work after delivery was completed. He had, of course, had good results in intermediate operations, but he preferred the immediate.

Dr. Charles Jewett of Brooklyn said he respected the rule that the obstetrician should, if possible, dismiss his patient in as good condition as he found her, but his experience with cervical lacerations led him to refrain from immediate repair, owing especially to the risk of infection. Directly after labor, in addition to the fact that the wounds were all fresh, the general resistance was lowered, the local resistance in the bruised and greatly softened cervical tissue was at a minimum, the operative field was in close proximity with the wounds of the uterine cavity, and the resorptive activity was at a maximum. For these reasons he dreaded the possible consequences of much intervention in the upper part of the birth canal immediately after labor. Ample experience had shown that the best puerperal results were attained only when the parturient tract had not been invaded at all during the birth, or at its close. In case of arterial hemorrhage from the torn cervix, usually immediate suture was of course imperative. In other parts repair was better deferred, at least until the tissues had in great part recovered their normal resistance, and the wounds of the uterine cavity were healed, or healing. In one case in which he had sutured the cervix the day following labor, and with the usual aseptic care, the woman developed a mild septic phlebitis. One of his colleagues had a similar experience. He preferred to wait not less than two or three weeks. Dr. Jewett said he agreed with Dr. Coe as to the importance of carefully searching for the location and extent of lacerations at the vaginal orifice at the close of labor, both anterior and posterior injuries, and of their immediate repair. This part of the tract could immediately be restored without risk of infection. The consequences of neglect were worse than in ordinary injuries of the cervix, many of which did not require repair at all. With reference to the time for operation on pelvic floor lacerations, the speaker said that some years ago, for teaching purposes, he adopted the plan of operating in most of his hospital cases several hours or days after delivery, and he had found that even after as many as seven days union occurred, and the results were entirely satisfactory. When necessary, the wounds were revivified by rubbing them with a gauze sponge. While he would not recommend this plan for general use, in simple cases he thought it had many advantages in dealing with extensive tears. It was often difficult to restore the parts properly at the close of labor, with perhaps a poor light and scant help, when the structures were badly distorted and the work obscured by the bloody flow from the uterus. A few hours or days later the operation was usually found to be a very simple matter. The condition of the patient sometimes contraindicated immediate repair. She might be too much exhausted. If the wounds became infected they would not unite, and the danger was increased by suturing. With reference to methods of repair, it was very essential in complete lacerations that the internal, as well as the external sphincter be restored. The normal control of the bowel depended in no small measure on the integrity of the internal sphincter. Instead of suturing the rent in the rectal mucosa, he liberated the lower portion of the rectal mucous membrane anteriorly, drew it down, and stitched it at the anal orifice. This shut off the wound from the rectum, and insured almost certain union.

Dr. Francis Foerster said the immediate repair of the soft parts after labor depended primarily upon the surroundings and environment of the patient, as well as her

condition. The proper method of procedure in the hospital could not always be carried out in private practice, especially in tenement houses. Hemorrhage, of course, demanded immediate attention. The speaker referred to the fact that after tears of the cervix of even considerable extent the organ apparently resumed its normal appearance when the congestion had disappeared, and for that reason he did not always consider it essential to repair these ruptures. In dealing with lacerations of the pelvic floor, they should, under favorable conditions, be repaired immediately. If that was impracticable, it was better, he thought, to wait two, three, or even four months before undertaking the operation. By that time the parts would be restored to their normal condition, having undergone similar changes as the uterine muscles, and better results could be obtained.

Dr. FRANK R. OASTLER said that personal observation of several thousand cervices in women who had had children demonstrated, (1) that a very large majority of cervical tears healed, leaving the laceration present, but giving no symptoms; (2) that of the others there were some where bilateral tears had extended to the vaginal vault and had healed, causing eversion of the cervical mucous membrane, and consequent disagreeable discharge and irritation; some where there was considerable scar tissue in the angle of the healed tears, accompanied by cervical metritis, leaving a large, congested cervix; and still others where the tear had extended deep into the broad ligament on one or the other side, causing considerable scarring. Extensive bilateral tears should be repaired immediately after labor, for by approximating the torn surfaces with one or two sutures the resulting eversion of mucous membrane was avoided. Where lacerations, however, extended into the broad ligaments it was better to pack and drain, for sutures were very apt to catch the uterine artery or ureter. There was no difficulty in obtaining free drainage following suture. Dr. Oastler said he believed that the ordinary bilateral and central tears involving the perineal body and extending into the lateral sulci for a short distance were of minor importance in causing perineal relaxation. The relaxation was found not at the vaginal outlet as a rule, but in the upper two-thirds of the vagina. He was inclined to attribute the latter to a weakness of the levator ani muscle resulting from minute subcutaneous muscle fiber tears in the upper two-thirds, or by partial paralysis of the muscle itself. This condition was caused by the constant pounding of the child's head upon the perineal floor, and stretching of a poorly developed muscle in a poorly developed patient. This stretching, or paralysis of the levator ani, could be avoided to a considerable extent by hastening the second stage of labor, even at the expense of a tear of the perineal body or its extension into the lateral sulci. The latter condition could be repaired immediately and successfully, but the former was often repaired with extreme difficulty. All vaginal tears should be repaired immediately after labor, unless the condition of the patient contraindicated it. They healed rapidly and well.

Modern Obstetric Technique.—Dr. GEORGE L. BROADHEAD, in this paper, limited himself to a few of the more important points in obstetric technique. Normal labor, naturally, received first consideration, and this subject, for convenience, he divided into three subdivisions: first, the preparation of the patient; second, the preparation of the accoucheur, and, third, the preparation of the lying-in chamber. In speaking of episeotomy, Dr. Brodhead said that in properly selected cases, and correctly performed, the operation deserved a distinct place in obstetric technique. Where there was need of haste, or when the head was large and the perineum began to tear when there was but little distention of the vulva, the operation was so easy and the results so good that he felt it ought to be performed more frequently. After discussing version, the various kinds of forceps operations, and the dangers incident thereto, Dr. Brodhead said that craniotomy had been regarded too long as a procedure so difficult and dangerous that it was considered only after all other measures of extraction had failed. As a matter of fact, the operation was frequently much easier than the high forceps operation, and, again, it was much safer for the patient than podalic version. In any labor where the child was dead craniotomy was to be preferred to a difficult forceps or breech extraction. For the induction of labor, of the three well-known methods, the gauze tampon, the bougie, and the hydrostatic dilators, the speaker said his preference was for the latter. The bags of Champetier de Ribes, in their present modified form, had given so much satisfaction that he used them almost exclusively. Under the heading *accouchement forcé* Dr. Brodhead discussed the various methods for the rapid dilatation of the cervix, namely, manual or digital dilatation, the use of a steel dilator such as the Bossi, and third, the use of rubber dilating bags. When there was no need of great haste, the Champetier de Ribes bags had been very useful, but for rapid dilatation the digital method was preferable. In speaking of cesarean section, Dr. Brodhead said the operation had grown steadily in popularity, and the results, for both mother and child, were sufficient to justify it. Symphyseotomy was now performed very seldom. Hebotomy or pubiotomy had been done about 300 times since 1894, when Gigli first proposed the operation as a substitute for symphyseotomy. Jewett claimed that it offered no advantages over the latter operation, and that it was open to all the objections which obtained in the usual median section. Personally, the speaker said, he believed that the field for the operation was very small, and that more satisfactory results were to be obtained by the induction of premature labor; or, if the patient had gone to full term, by the operation of cesarean section.

The Urine in Pregnancy.—Dr. FREDERIC E. SONDERN read a paper on this subject, in which he stated that recent advances in the chemical investigation of urine in pregnancy had resulted in much of value to the obstetrician as an aid to his work, and in the correction, or, more properly speaking, modification of previously held views. When dealing with laboratory aids in diagnosis or prognosis, to prevent being misunderstood, it seemed necessary to frequently repeat that they were aids only, and it was well to add with all possible emphasis that all laboratory procedures, no matter how important, never took the place of clinical observation. It was the clinician who was the most acute bedside observer that received the most help from laboratory aids, for he was generally also well informed as to the value and significance of the changes from the normal noted in laboratory investigations. While the periodic examination of the urine in pregnancy, for gravity, albumin, sugar, and casts no longer met with the exacting demands of present day diagnostic methods, on the other hand no specified change from the normal in any respect could be accepted as a prime indication for drastic therapeutic measures or operative procedure, though it was oftentimes a material help in concluding the existing necessity for such. The demonstration in general that intestinal intoxication, intestinal toxemia, or faulty intestinal metabolism, whichever term or view one might prefer to accept, was the cause of a distinct train of symptoms, and often explained other obscure manifestations, was now a recognized fact. When it was recalled with what facility disturbances of the gastrointestinal tract were occasioned in pregnancy, and mindful of the experience that intestinal autointoxication frequently seemed to be the forerunner of the toxemia of pregnancy, if not more closely allied in the etiology, the necessity for early diagnosis of this condition was evident. The clinical manifestations which directed attention to this intestinal autointoxication were not within the province of this paper, but the laboratory aid in its diagnosis was imporant, and it was the recognition of a relative excess of ethereal sulphates in the urine. As

indoxyl sulphate and skatoxyl sulphate were the varieties most frequently present in excess, a test for this excess should form part of every urine examination in pregnancy. As in general medicine, so in obstetrics, the occurrence of albumin in the urine, alone or associated with casts, was no longer the bugbear it formerly was, as we knew that it did not necessarily indicate an inflammatory lesion of the kidney. While the occurrence of a so-called physiological albuminuria was open to question, on the other hand, with comparatively slight disturbances in circulation, in innervation, or in the quality of the blood offered it for the exercise of its function, the kidney passed smaller or larger amounts of albumin, with or without casts, indicating disturbed function not necessarily due to an inflammation of its parenchyma. It was essential to keep these general considerations in mind when attempting to interpret a urinary picture. The frequency with which albumin was now found in the urine as compared with former times was due to more diligent search, rather than to its more common occurrence. Recent investigations had shown that approximately 50 per cent. of pregnant women showed albumin in the urine at some time during pregnancy. These high figures were easily understood when considering the many causes occurring in pregnancy, such as circulatory disturbances, faulty innervation, irritating excretory products, and increased functional activity, in addition to the presence of actual renal lesions. The numerous possible causes rendered the differential diagnosis by no means an easy matter, and the apparently physiological retention of nitrogen toward the end of pregnancy added another difficulty. Dr. Sondern said that continued experience in the analytical work in connection with these cases would seem to indicate that the practical conclusions were that the routine urine examination of pregnant women should include a search for evidences of faulty intestinal metabolism, so that this apparently predisposing factor might have early attention. On occurrence of any of the clinical signs of toxemia of pregnancy, the degree of acidosis should be determined, and should this increase, then a repeated nitrogen partition would lend aid in determining the point beyond which it was not safe to allow the patient to go.

Dr. Samuel M. Brickner said he agreed essentially with Dr. Sondern, and referred to the recent advances that had been made in our knowledge of the urine of pregnancy. As late as 1850, Schroeder, in referring to this subject, simply said that most pregnant women had a little albumin in the urine, and that the urine was apt to be a little more watery than usual. Now, in addition to the search for albumin and casts, it was essential to obtain an accurate determination of the nitrogen partition, and the actual chemical examination of the urine during pregnancy had become such a complex matter that it was scarcely within the field of the general practitioner or of the obstetrician. In connection with this subject, Dr. Brickner said, there were two or three points that he wished to emphasize. One was that there could be no decided pathological change in the urine without some corresponding clinical manifestation. Whether the reverse of this held true he was not prepared to say, but where the urine showed an acidosis, or where the relation between the total amount of nitrogen output and ammonia was at fault, we could expect to find corresponding clinical manifestations. They would be revealed by close questioning, although the patient may not have complained of them. There would perhaps be headache, mostly frontal, nausea, or vomiting, or both; or we might find scotomata or some abdominal pain in the epigastric or hepatic region. These he regarded as the cardinal symptoms in cases of this kind. Some of the most serious cases he had seen were in elderly primiparæ, and they were more apt to be met with in women above the age of 30 or 32. The speaker said it had occurred to him that the various types of the so-called toxemia of pregnancy were apt to merge into each other.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 19, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	450	181
Diphtheria	313	37
Measles	186	6
Scarlet Fever	239	9
Smallpox	—	—
Varicella	125	—
Typhoid Fever	34	12
Whooping Cough	68	9
Cerebrospinal Meningitis	16	9
Malarial Fever	..	..
Totals	1431	263

Traumatic Decapsulation of the Kidney.—M. K. Helly reports this case. The patient, a young man twenty-one years old, fell from the first story of a house and was carried to the hospital with symptoms of abundant intraperitoneal hemorrhage. Laparotomy revealed the existence of an extensive rupture of the liver. The patient succumbed soon afterwards. At autopsy there was also discovered a total decapsulation of the right kidney without any other lesion of this organ. This decapsulation had probably been produced by the strong compression made by the floating ribs at the time of the fall. The kidney had been expelled from its torn capsule as neatly as the stone from a cherry.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 18, 1907:

THE INTERLUDE OF CANCER.

BY JOHN BEARD, D.Sc.,

EDINBURGH.

In preda al duol non mi lasciar!
Intermezzo in *Cavalleria Rusticana*.—MAZZONI.

IT is a wise child of investigation which knows its own scientific godparents. Mine were two men of supreme brilliance and great eminence, Johannes Müller and Carl Ernst von Baer. What I owe to their examples and to their work can never be expressed adequately, and as little can it ever be estimated to what extent mankind is indebted to them. These deeds of theirs, which as I write pass through my mind, were all determined attacks, prolonged and well-sustained assaults upon the problems of the nature and mode of animal development.

Neither Müller nor Baer, it is true, laid down any law of the life-cycle from generation to generation, because each of them in his final research stopped just short of the point, at which the crux of the problem would have asserted itself. Neither investigator spared himself in the task. Indeed, von Baer writes: "Thus, it came about in a certain year, that I shut myself up in my shell, when the snow still lay on the ground, and that later on, going for the first time to a wall a few hundred steps away, I beheld the barley in the ear and almost ready for harvest. At this sight I threw myself on the ground, and made myself reproaches for my foolishness. 'The developmental laws of Nature will be discovered,' said I to myself in Epicurean or Mephistophelean fashion, 'and it is a matter of indifference whether it be by you or by others, whether this year or some time in the future.'"

Müller died in 1858, before my birth, and, although von Baer lived into the seventies, from the time of the Königsberg researches (1819-1834) he never again worked seriously at the problems of animal development. In a sense it looks like a mere accident that the thread of research, dropped by Carl Ernst von Baer so long ago, should have been taken up enthusiastically, under far more auspicious circumstances, by a young man of less than thirty years of age in 1888, who was working in the Anatomical Institute of the University of Freiburg, Berlin. Prior to then he had been trained severely by A. M. Marshall, Huxley, and Semper. At that time, and for many years afterwards, he little dreamt that, regarding the work from its human aspects as opposed to the far wider, higher scientific ones, he was really working out the problems of cancer. Indeed, without then knowing it, these had actually been solved in researches published by him in 1896 and 1897.*

The embryologist never tells the story of his work in the order of his researches. He cannot, for in these he pushes his way little by little, step by step, from the known to the unknown, and at any given time he may be working in two directions, upwards from the starting point of the fertilized egg, and downwards from the finished embryo. Thus, it happened, that what, logically regarded, should have been the first investigation in 1888, the history of the germ-cells, was actually the last, as it was also the coping stone, which crowned the work, and made it lasting.

The actual cancer-researches have been a mere interlude in the whole—an intermezzo. "The prey of pain let me not be!" The solution of the problems of cancer was but a corollary of what had gone before, and it followed naturally and irresistibly out of the germ-cell results, the course of the life-cycle, and the conclusions as to germinal continuity and heredity. Since the embryological theories of the textbooks are, to apply the words of Pasteur, a mass of baseless hypotheses, it follows

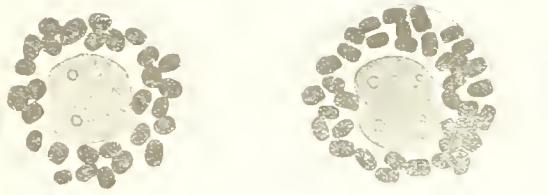

FIG. 1. FIG. 2.

Illustrating the Germ-cells of Fishes and Their Migrations into the Embryonic Body.

FIG. 1.—Primary germ-cell of a small dog-fish, *Pristiurus melanostomus*. The cytoplasm is glassy in character, and contains a large number of (blackened) yolk-plates. The nucleus exhibits chromatin, *i.e.* autonomy of paternal and maternal portions.

FIG. 2.—A similar primary germ-cell from the skate, *Raja batis*.

that the solution of the problems of cancer can be grasped properly only by a comprehension of the course of the cycle of life from generation to generation, as my researches of the past eighteen years have revealed it.

The starting point of a new cycle is the fertilization of an egg and the outline history of the cycle is not complete until we have shown how new eggs, new reproductive elements, arise, and until we have reached the point at which these are ready for fertilization, to start the cycle anew. An egg is fertilized and development begins by its cleavage, an ever-increasing number of cells is formed in this way, and anon we reach a point at which the orthodox embryologist says that the egg-cleavage is finished. What has then come into being? The usual reply is "a new organism, an embryo." No such thing! At the close of cleavage in none of the higher animals is any trace of an embryo present. Something is there, but not an embryo. I will ask the reader to regard this developing egg from the start of cleavage as a living organism, but not an embryo.

The criterion of anything in embryology is the fate or destination of the cells. In a worm's egg, which has cleaved five times, giving 32 cells, or in a skate's egg, which has undergone ten divisions, resulting in 1,024 cells, there is not a single cell

*J. Beard, On Certain Problems of Vertebrate Embryology (The Critical Period), and the Span of Gestation and the Cause of Birth, 1806 and 1897, Jena, Gustav Fischer.

present which is embryonic in destiny. Nearly all the cells are predestined to form portions of an asexual foundation or larva, termed by me the "phorozoon," or bearing animal. This is a transient organism, for as a rule its life is very brief. It has a part to play in the cycle, and, like the Moor, when it has done its appointed task, it can go. The results upon which, generally speaking, my conclusions are founded have been obtained by what my late friend and teacher, Professor George Bond Howes, Huxley's assistant and successor, was wont to term the comparative morphological (and physiological) method. Under it there is but one mode of development for all the higher animals, in essentials the life-cycle is always similar, not only from fishes to man, but from worms and even lower forms to fishes. These "phorozoa," or asexual generations of various marine organisms, have long been known. Often, and until a connection therewith was established, they received names distinct from those of the sexual generations. Thus, the larva, "phorozoon," or asexual generation of a brittle star is still known as a *Pluteus,* and so on.

The late Professor N. Kleinenberg first set up (1886) the doctrine of development by substitution of organs. Under this every organ of the larva (asexual generation) was ultimately replaced by a corresponding, but differently developed, organ of the adult form (sexual generation). For a variety of reasons, into which space forbids entry here, it soon became clear to the writer that Kleinenberg's doctrine was inadequate, and that, instead of a substitution of organs, there was in development in reality a substitution of organisms. The sexual organism replaced the asexual one. This was seen to be an alteration of generations, and as there was no homology or close likeness between the asexual generation or its organs and the sexual form or its organs, it was an antithetic alternation of generations.

Now that we have the first mention of the word "antithetic," it may be permitted in passing to point out how Pasteur's researches started in the antithesis of the two sorts of tartrate crystals, mine in that of two nervous systems in the life-history of a fish. Here we are dealing with anatomical antitheses; later we shall come to recognize physiological antitheses, that of two ferments.

The tracing of the asexual generation in the backboned animals or vertebrata, from fishes to man, was not without its own special difficulties. These were due rather to expecting too much, and to failing at first to realize that the higher one ascended in the scale of life, the greater became the organization of the sexual form or generation, and the more insignificant the asexual one, until in the highest animals, the mammals and man, the asexual generation became reduced to the almost structureless chorion or trophoblast, as Professor A. W. Hubrecht named it in 1889. Many people, quite ignorant of all the embryological advances of the past twenty years, appear to imagine that I not only introduced the name "trophoblast," but also invented the thing to which it is applied in embryology. These things are not true. The name was invented for a thing defined by Hubrecht in 1880, and the thing itself has existed for untold millions of years!

Quite eleven years ago, in 1895, the standpoint had been attained that in every life-cycle of a higher animal, such as man, there were two generations, an asexual one, the trophoblast, and a sexual one, the metazoan individual or person. The puzzle was not how the first of these arose, for clearly it could be demonstrated any day in the week that it was the direct product of the cleaved or segmented egg (vide Fig. 5, phorozoon or larva). Somehow or other there arose gradually upon it the sexual generation, by a process of evolution or unfolding.

TABLE OF REVISED COMPARISON OF ANIMAL AND PLANT LIFE-CYCLES.

	ANIMAL.	PLANT.	
Asexual Generation.	Zygote or fertilized egg (2n).	Zygote or fertilized egg (2n).	Asexual Generation.
	Phorozoon or trophoblast.	Sporophyte or flowering plant (2n).	
	Formation of primitive germ-cell (2n).	Formation of primitive spore-mother cell (2n).	
	Formation of primary germ-cells (2n).	Formation of spore-mother cells (2n). (Reduction and sex determination.)	
	"Apospory" (reduction postponed).	Spore-formation.	
Sexual Generation.	A primary germ-cell (2n).	A spore (1n).	Sexual Generation.
	Origin of embryo by unfolding of a primary germ-cell, inclusion of rest in the individual of the sexual generation (2n).	Origin of sexual generation or gametophyte from one spore (1n).	
	Ripening of germ-cells. Reduction and sex determination.	Ripening of germ-cells. Reduction previously effected.	
	Sperm Egg	Sperm Egg	
	Zygote	Zygote	

In the above table "n" equals the reduced number of chromosomes, and "1n" signifies the emancipated cell, "2n" the duplicated or conjugated cell, the "conjugation" or joining together being carried out at fertilization. The "reduction" is the undoing of the previous duplication effected at conjugation.

How? Something resembling the spore-mother-cells of plants was required. That was very apparent. (See the table of Revised Comparison.) It was not until towards the close of 1900, when the first harvest of the germ-cell-researches had been reaped, that the problem was cleared up. The germ-cells arose *before* the embryo, as products of a single cell, the primitive germ-cell (U.K.Z. of the diagram, Fig. 5). They came into being upon the asexual generation or trophoblast. To contain and to nourish these germ-cells for a brief span of time another organism was needed, a sexual one, endowed with sexual organs.

How was the sexual organism obtained? In embryology things do not come into existence out of nothing! True, there are embryologists who look upon holes or cavities as the sources of important organs, but the writer at all events is *not* a "hole-morphologist"! The unit from which anything arises is the single cell. There was only one source from which such a sexual generation could arise; this was by the evolution or unfolding, the self-sacrifice, of one germ-cell for the well-being of the rest, and to contain them. At the epoch of the formation of the primary germ-cells all were alike in origin and potentialities. All were so many potential individuals of the species. If two developed independently, the result would be identical twins, if three, triplets, and so on.

Reviewing matters, starting with the fertilized egg, this gives rise to an asexual generation, the trophoblast, upon which there arises an "apical cell," the primitive germ-cell. This latter divides a certain limited number of times, this number being a fixed one for the species, but while it is *n* in the male, it is *n* plus one in the female. The products are 2, 4, 8, 16, 32, 64, 128, 256, 512, etc. In the diagram it is depicted as 128. These 128 germ-cells are the primary germ-cells. It is they which enter the embryonic body (Fig. 4) when this arises, and it is some of them which come to occupy all sorts of abnormal positions. But all the line of primary germ-cells are not destined for future generations. Some few of them, 1, 2, 4, or 8, are embryonic in destiny. At least one of these must unfold to form an embryo. If any of the others do so, the result is identical twins, triplets, etc. If any of these "embryonic" germ-cells lie dormant within the developed embryo, they may become the seed of future tumors, as will appear later on. The line of heredity so far revealed leads from fertilized egg to the primary germ-cells, and thence through all the history of the germ-cells within the "reproductive glands" to new eggs and sperms. That is, all things considered, the cycle is one of unicellular organisms, the germ-cells, in the history of which the sexual generation of individual is but an incident.

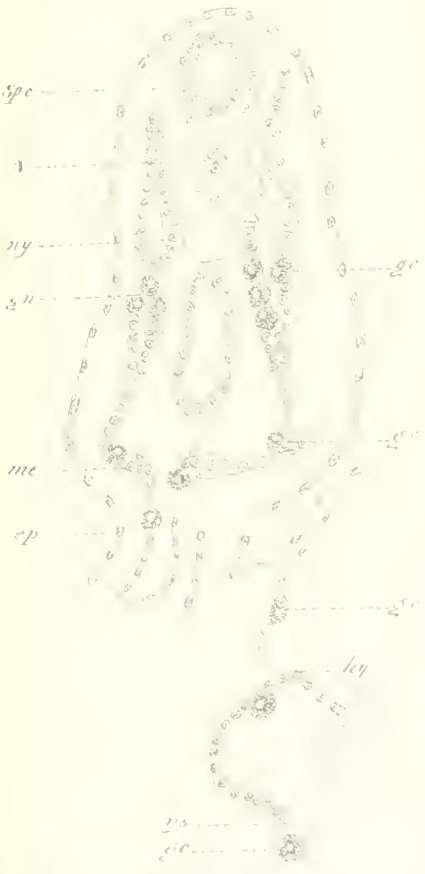

Fig. [illegible] Two conditions seen in two transverse sections of a 4½ mm. embryo of Perameles. The letters mean as in last figure: *spc*, spinal cord; *n*, notochord; *my*, myotome; *gm*, germinal mass; *me*, mesoblast; *ep*, epiblast; *hy*, hypoblast; *ys*, yolk-sac; *gc*, germ-cell.

Another important question to be solved more than ten years ago was the how and the when of the suppression of the asexual generation. This latter, whether represented by the transient nervous apparatus and other structures of a fish, or by the trophoblast of a mammal, went on flourishing for a certain, not very long, space of time, and then, quite suddenly, all growth was stopped, and its degeneration was initiated. In years long gone by how often have I not watched these asexual structures under the microscope, seen them flourish and bloom, and then—*subito*, as the Italians say—begin to fade away, as though blighted! The correlation of phenomena is often of the greatest importance to the embryologist in his work, and when this sudden fading away was first established, it was also noted that the commencing formation of the posterior fissure of the spinal cord was a concomitant phenomenon. This led to one of the many little research excursions I have made right up the backboned series to the mammals, and to the study of human embryos themselves. A whole array of interesting and connected events was soon unearthed, and the putting together of these culminated in the discovery of the critical period—one of the most momentous finds ever made!

"There is a period in the development of every vertebrate embryo, during which, and only then, it resembles the embryo of any other vertebrate in a corresponding phase in certain general features. But, while it thus agrees exactly with any other embryo of this period in characters, which are common to all vertebrate animals, it differs from the embryo of any other class in certain special class features, and also from any other embryo of the same class, but of a different order in other and ordinal characters. Immediately before this period is reached it begins to put on generic and specific characters, and thus it then begins to differ from all other embryos in these." In other words, the embryo then first asserts its presence, announces its own individuality. It is then first present as a complete thing. It then first begins to use its own digestive apparatus, especially its pancreas gland, and in a higher mammal to feed itself by means of the allantoic placenta. This critical period is common to all backboned animals in their development. At this period the average marsupial is born into the world, and then it first begins its long mammary nutrition. In so great a hurry is it to get into the world that it forms its anus in the act of being born. The human embryo does the same at the like period, in the seventh week of gestation, as though it were a marsupial, although it has no use for this aperture for many months to come. Then the allantoic placenta, an organ of the embryo or sexual generation, like the pancreas-gland, first begins to function, and then normally the trophoblast begins to fade, to be suppressed, and to degenerate.

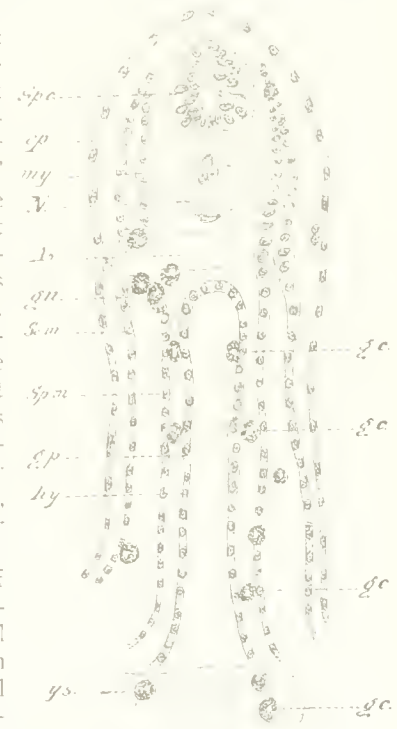

Fig. [illegible] A diagrammatic section of an early skate-embryo. The letters illustrate the migrations of the germ-cells along the germinal path, [illegible] the resulting germ-cells in various abnormal post-embryonic situations. The letters mean as in Fig. 1, except: *gm*, germinal mesoblast; *spm*, planc[illegible] mesoblast; *ao*, aorta.

Though ferments first made their appearance in my published writings in 1892, for I pride myself on having been one of the very few pupils the late Professor C. F. W. Krukenberg ever had, it was not until 1904 that their all-important bearings upon the critical period were evident. In human gestation, if at the critical period the embryo be wanting [illegible] very abnormal or very abnormal human embryo can only exist as one of identical twins), the characters of the critical period are lacking, and [illegible] always begins [illegible] the uterine epithe-

lium and wall, may go on with this process, exhibit indefinite powers of growth, and eat its way through uterus and other organs, finally blocking the lungs and brain of the mother. This is chorioepithelioma, recognized to be a form of cancer by Professor F. Marchand, in 1895. This is without doubt the most deadly form of cancer. Here the sexual generation being unable to suppress the asexual one or trophoblast, the latter exhibits the characteristics of asexual generations, the powers of indefinite growth and increase. Pathologists at present distinguish wrongly between two forms of chorioepithelioma, a malignant one and a benign one. The latter has no real existence, for in it the trophoblast cells are all dead and undergoing the characteristic degeneration due to the action of pancreatic ferments. A "benign" chorioepithelioma, as Professor Schmorl found, may happen in any gestation, for the trophoblast cells of the precritical periods, which have invaded the maternal organs, even the lungs, are normally also brought to commencing degeneration at the critical period.

In 1902 the conclusion was reached that cancer was an irresponsible trophoblast, and in these words for the first time in human history the *nature* of cancer was laid bare.

Its *origin* was not at first so clear, but by the year 1904 it was recognized that the problems of like or identical twins, upon which the writer was then and since engaged, threw light upon its origin. Owing to their extraembryonic origin aberrant germ-cells are quite common, and they may be met with anywhere in the embryonic body. The ordinary aberrant germ-cells, which usually degenerate, were much too abundant a source to furnish the origin of a cancer. *Entia non sunt multiplicanda.* The etiology of double monsters and of malignant tumors was traceable to the phenomena of like twins. The facts concerning these, as well as those relating to Hermann von Jhering's finds in the armadillo, *Praopus hybridus*, which my work has fully confirmed, furnished the key. This armadillo, the "tatu," produces all its young in one chorion or trophoblast, and therefore they are all identical, of the like sex, and all products of one egg. The whole doctrine of the tumors, benign and malignant, centers in the phenomena of like twins, that is, in a former multiplicity of embryos, all products of one egg. To-day the "tatu," *Praopus hybridus*, produces 7 to 12 such, all derived from a single egg, all of the like sex, and *some of them more or less rudimentary!*

These latter tell a very significant story* to the

*Because hypothetical, the following may find a place as a foot-note: From the consideration comparatively of a variety of embryological phenomena, well known to the investigator, it is obvious that the procedure where only a single embryo is going to arise from one of the primary germ-cells will not be quite the same when two or more embryos are destined to unfold. The setting apart of one cell will be preceded by one or two divisions, giving one functional cell and possibly three abortive ones. But if the development shall result in, say, triplets, there will be not merely two divisions, but at least three, if not four. Of the products which are all primary germ-cells, three will form the embryos, these may be abortive or rudimentary, and if there are eight cells, two will remain as germ-cells, which later on in some or other of the individuals arising may become the seed of tumors, benign or malignant. But these cell divisions have a curious tendency to be in twos or pairs, or even in threes, so that in the formation of triplets, instead of eight cells, there may be sixteen concerned. How many of these will be abortive, and how many "embryonic" in potentialities, it is at present impossible to say. The armadillo, *Praopus hybridus*, with its seven to twelve young in one chorion or trophoblast, affords an instance where at least sixteen cells must originally in every case have arisen at the line of primary germ-cells, and in addition to these cells destined

embryologist. They recall to him other similar phenomena in embryology. Reductions in numbers of units (cells), formerly of importance, but which now persist, not because they are really required, but because their existence and persistence are parts of an old scheme of the cycle of animal life.

The writer has had abundant opportunities of noting the liability of identical twins to cancer, but to state the matter in this way is misleading. Those individuals who develop malignant growths are as liable to such as are identical twins, and for the same reasons. Without doubt cancer is hereditary. This is abundantly borne out by clinical histories in my possession. There are records, where both parents died of it, where even one or other grandparent developed cancer, and it is only too commonly told the writer that in some particular case the father

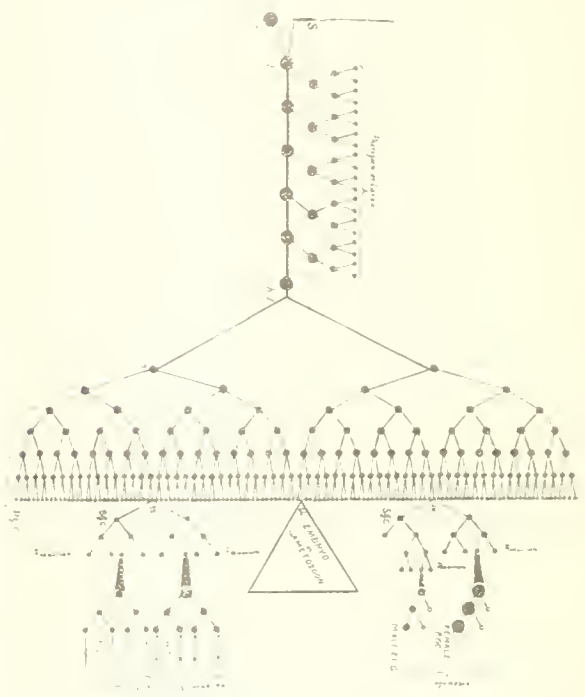

FIG. 5.—Diagram of the life-cycle of a backboned animal, such as a fish or a mammal, illustrating the union of egg and sperm, E. and S., to form the zygote, Z., the origin of the phorozoon or asexual generation (trophoblast), the germinal track from Z. to U.K.Z., the latter being the primitive germ-cell. The divisions of the latter are carried to seven mitoses or cell-divisions, as in some male dog-fish, in a potential female embryo there would be an additional division, giving 256 primary germ-cells. Diagrammatically, the unfolding of one primary germ-cell, the 65th, is depicted as forming an embryo or sexual generation. To complete the track of heredity from generation to generation through the morphological continuity of the germ-cells a diagram of oogenesis or egg-formation has been appended to the 96th germ-cell, and one of spermatogenesis or sperm-formation to the 32d. In the former the formation of a male-egg and of a female-egg is shown, in the latter the two forms of sperms (as in the fresh-water snail, *Paludina*, after the statements of F. Meves) i.e. the hairlike or functional, and the wormlike or functionless sperm. The additional division in the formation of functional male eggs should be noted. It accords with the additional division to form primary germ-cells in the development of a female.

or the mother was a victim of cancer. The most remarkable example known to me at present is in the family of a master-carpenter in Edinburgh. His mother died of uterine cancer, and he has lost all his brothers and sisters, seven in number, by some form or other of malignant disease. Embryologically regarded, persons suffer from cancer because they are at the basis members of a group of identical twins or triplets. It is, therefore, not from any and every aberrant germ-cell that a cancer takes its

become the sexual products. Of these sixteen cells, seven normally give rise to fully developed embryos, five to more or less rudimentary ones, and there still remain four, which, as cancer is not known here, may be abortive. But if the number of young here arising at every gestation were much reduced, while all the preliminaries were retained, what a rich harvest of tumors might be the result! In a case of identical triplets, cited by Prof. H. H. Wilder, at least two of the sisters died of cancer

start, but from one or other of some few germ-cells, embryonic in destiny, cells which should have given rise to twins, triplets, etc., identical with the embryo, which arose in any particular gestation.

The line of primary germ-cells of the diagram (Fig. 5) is not made up of one only, destined to form an embryo, and of *n* minus one, destined for a future generation, but it is composed of a limited number, 2 or 4 or 8—often not so many— embryonic in destiny, of which, as a rule, one only becomes a normal embryo, and n minus 2, or n minus 4, etc., are set apart to provide for the cycle of unicellular organisms or germ-cells. Such a persistent embryonic germ-cell, encapsulated within the individual, may at any time, by illness, injury, irritation, or other cause, such as declining years, weakening the system, be awakened into activity. The "age-incidence" of cancer is scientific nonsense, for it is only relative. Whenever this happens, the time is long past when it should have unfolded as an embryo, it attempts to resume the cycle, and its "unconscious memories" only enable it to try to repeat the asexual portion of the cycle. Such an encapsulated germ-cell can only do one or other of two things in the end, *and live*. It may develop, and it only does this congenitally with the developing individual, or it may attempt to go on with the life-cycle. Skipping the formation of conjugating cells or gametes, it is brought to the next portion of the life-cycle, trophoblast. In this way it becomes an irresponsible trophoblast, and it may imitate or mimic anything in its environment. Whatever it mimic, something existent or non-existent, it is always an "imitation tissue," and behind the domino or mask an irresponsible trophoblast.

In nearly all the foregoing morphological aspects have been under consideration. It now behoves us to take account of the physiological and functional ones. The critical period in a fish or mammal or man is that at which the embryonic organs as a whole first begin to function. The fish begins to feed itself, digesting the yolk by intestinal digestion. The mammal or human embryo begins to do the like (in the absence of food-yolk) by means of the commencing functional activities of the allantoic placenta. At this epoch in the fish the pancreas-gland manifests its activities by the presence of abundant zymogen granules in the cytoplasm of its cells. That these result in the secretion of pancreatic ferments is shown by the digestion of yolk within the gut. Owing to this digestion the fish, like the mammal, gets ever bigger and bigger. None of the yolk enters its stomach, for this has then as little functional activity as the stomach of a mammal has during fetal life. An internal yolk-sac is formed for the reception of the yolk from the external one, and the yolk duct opens into the duodenum. This fact alone indicates to the embryologist that the pancreas gland is functioning. In an average marsupial at the critical period this gland certainly begins its functional activities, for the animal is then born, begins its mammary nutrition, and digests the milk. If a certain thing happen at the critical period of a fish, or a marsupial, I know from experience that something corresponding to it will take place at the like period in a higher mammal or a man. A fish forms its anus at this period, so does a marsupial, while in the act of being born, and so does a man, although he does not need it for some seven months more. As the pancreas gland begins its functions in a fish or an average marsupial, so it must do in the development of a man. Otherwise there would be no essential unity in the mode of the development. Undoubtedly, under the action of the pancreatic ferments, the asexual structures of a fish development begin to degenerate, and, as represented by the trophoblast, they do the like in a mammal or a man.

This leads to an inquiry as to modes of nutrition, regarding which the reader may find much interesting information in Verworn's "General Physiology," and still more in Otto von Fürth's "Vergleichende chemische Physiologie der niederen Tiere, Jena, 1903. The unicellular organisms or protozoa, all asexual generations of animals, such as invertebrate larvæ, fish blastoderm, and mammalian trophoblast, not forgetting cancer cells, nourish themselves intracellularly and by means of a ferment acting in slightly acid medium. On the other hand, an extracellular digestion, by means of ferments, pancreatic enzymes, acting in slightly acid, neutral, or alkaline media, is restricted to the sexual generations or individuals of the higher animals (Metazoa) and man. In the former the ferment is possibly always the like one, and it would possibly be, to my mind, identical with the cancer-ferment, discovered by Eugen Petry in 1890, and which I have named "malignin." The ferments of the sexual generations being much more powerful than the intracellular one found in the forms referred to above, being, indeed, the most powerful things in the whole range of organic nature, it would follow that just as these higher ferments destroy in life the living cells of malignant tumors, pulling down their albumin, so also they must destroy the organisms, usually asexual generations, of tuberculosis, sleeping-sickness, malaria, yellow fever, etc., when injected into the blood by means of hypodermal medication. Regarded from the strictly scientific standpoint of the embryologist, who is "not even a medical man," the tubercle bacillus, like the trypanosome, or the organism of yellow fever, or that of malaria, etc., can no more live in the presence of these higher ferments than the cancer cell can. This has apparently been shown, in one case at least, clinically and pathologically for the tubercle bacillus by my friend, Dr. Margaret A. Cleaves of New York City. The first case of cancer which it fell to her able brain and skilled hands to treat by means of injections of pancreatic ferments, was also complicated by tuberculosis of the bowel. When, in August, 1906, the first communications passed between us, I informed Dr. Cleaves that, in my scientific opinion, whatever happened to the large masses of rectal cancer present, which appeared too great to leave room for hope of their entire removal, the tubercle bacilli would be bound to go. They disappeared, and after amylopsin had been injected for some little time the pathologists failed to find a single tubercle bacillus in the discharge, where previously they had been abundant. In our joint opinion the result was due rather to amylopsin than to trypsin, for the former is the medium of all others, in which the leucocytes can act. As in the treatment of cancer, the injection used against any of the above human inflictions should be an extract, freshly prepared from the pancreas-gland direct, and containing all the ferments especially the one in the presence of which the leucocytes act, *amylopsin*.

Of the ferments of the sexual generations by far the most important is that first discovered by the Court physician, Baron Corvisart, and to which afterwards Prof. W. Kühne gave the name of "trypsin." It is this enormously powerful ferment, trypsin, upon which Nature relies for the suppression of trophoblast in normal mammalian gestation. Lower down in the scale than the mammals she associates with it its complement, amylopsin. Fetal

blood of a mammal does not contain this latter, and the fetal pancreas-gland does not produce it. In the human pancreas-gland amylopsin is not formed until some few months after birth. The reason of this is not far to seek. When in the ancestral mammals uterine development was initiated, along with it and following its close there was evolved the mammary nutrition. In this amylopsin is not needed, and its production by the pancreas-gland was postponed until the milk-nutrition was done with. The mammary nutrition is (on the testimony of more than one embryologist, thus on that of my friend, J. P. Hill, as well as on my own) older in time than the allantoic placenta. The latter was introduced to defer the birth period, and by prolonging the gestation, as detailed in my "Span of Gestation," to bring the young into the world in a more perfect state. In prolonging the gestation, the mammary nutrition was postponed, and in this way the appearance of amylopsin upon the scene put off to an even later period. This has led to grave difficulties and dangers in human gestation, for there is no such thing in nature as a ferment possessing both proteolytic and amyolytic powers.

The proper scientific treatment of cancer is the enzyme or pancreatic one. If trypsin alone be used, bad symptoms very soon arise, all of which recall the vomiting of pregnancy and eclampsia. Trypsin alone is a very deadly remedy for cancer! The reason being that in killing the cancer albumin this enzyme does not split it up to harmless simple products. What the products of the action of trypsin alone are it is impossible to say, for they may quite conceivably vary with the amount of the injection and with its strength. Anyway, some of them are rank poisons to the organism, and they lead to nausea, vomiting, pain in the back, drowsiness, high arterial tension, albuminuria, edema, etc., and even to convulsions lasting several hours. The cause of such symptoms and of the eclampsia of pregnancy did not long puzzle the embryologist, who perceived that it was the absence of the complementary ferment, amylopsin, which induced them. Nature had committed a grave error in omitting amylopsin from fetal blood, and in relying solely on trypsin. In normal gestation if anything went wrong with the maternal pancreas-gland, and if the maternal supply of amylopsin became diminished or ceased, then serious symptoms were bound to follow. To my knowledge at the moment of writing injections of amylopsin have not yet been given in any case of eclampsia, but they have, whenever used in cases of cancer, removed all the bad symptoms named.

The preparations employed in the enzyme treatment of cancer should be like the sole ones in use in America, the Fairchild preparations. That is to say, they must be potent extracts, scientifically prepared from the fresh gland direct. The trypsin injections must contain all the enzymes and be especially rich in trypsin and amylopsin. The injection of amylopsin is to be used at all times to meet and remove all bad symptoms, and in the later periods of treatment, when all the cancer albumin has been destroyed, and it must be an extract of the pancreas-gland free from trypsin.

This treatment is not intended for use against benign tumors, which are composed of real or somatic tissues and which are not killed or broken up by trypsin. Owing to this the injections furnish a chemical test of the true nature of a tumor, whether it be benign or malignant. Thus, some pathologists look upon adenomata as benign, or at all events as only potentially malignant. To my mind they are "imitation tissues," and I should anticipate that any and every adenoma would yield to the chemical test.

Owing to the circumstance that the cycle of life is really a continuous procession and succession of unicellular organisms, germ-cells, from which there arise asexual generation or trophoblast, and embryo or sexual generation, the tumors can be classified into three groups, as follows:

(1) *Embryomata.* Benign neoplasms. Pathological manifestations of some greater or less portion of the sexual generation, "the embryo." They are composed of real tissues, that is, normal or somatic ("embryonic"), cells or tissues. At its basis each is a greater or less portion of a twin, triplet, etc., identical with the individual containing it. They are now endowed with indefinite powers of growth, and they nourish themselves like other normal tissues.

(2) *Amphimixomata.* Malignant neoplasms. Combinations of embryomata and trophoblastomata. Pathological manifestations or attempts to reproduce the whole life cycle, including trophoblast and embryo. They are transitional forms. (The mixed tumors of Wilms are not all malignant, some being merely embryomata.)

(3) *Trophoblastomata* (cancer and sarcoma). Malignant neoplasms. Pathological manifestations of the asexual portion (trophoblast) of the life cycle. They are not known to differentiate functional gametes, eggs, or sperms. They never include or repeat any part of an embryo. They are never composed of somatic ("embryonic") cells, though they may mimic such or even resemble no other cells in the body. As Fleischmann, Paget, and Bland Sutton pointed out, they are "imitation tissues." They exhibit powers of unlimited growth and increase, and they nourish themselves by eroding and destroying normal cells and tissues in a manner exactly like that of the trophoblast of normal gestation, and by means of a ferment acting intracellularly, viz., malignin.

As the two latter divisions are made up of malignant tumors, it is for them, and not for the members of the first group, that the enzyme treatment is intended.

In the foregoing simple story I have endeavored to the best of my ability to give in outline some idea of the course and nature of my scientific work and conclusions since the days of May-June, 1888, when I worked on the shores of Black Lake, New York. Much has happened since then, not only in my own little field of work, but outside of it. It is since that time, that is, in 1889, that Hubrecht set up the name "trophoblast" to replace with a different significance the older term "chorion." Long after then came the period of my germ-cell researches, not yet completed. These have, however, extended so far that they are revolutionizing embryology. In the light they throw on phenomena, the old Wolffian idea of epigenesis, and the allied Cohnheim hypothesis of embryonic "rests" as the sources of tumors, along with many other things, become memories of the past in science. The night is far spent; a new sun is arising. Epigenesis, somatic origin of germ-cells, and recapitulation in development are fading away into thin air before the mighty powers of Evolution with predestination, an actual tangible continuity of germ-cells from generation to generation, and an antithetic alternation of generations as the mode, the only possible one, of animal development.

This present writing is not the record of my scientific work. It is but a brief sketch of some of

the things my "brigades" and "divisions" have done or can do. He who would venture to attack them may be invited to turn his attentions to the original memoirs, representing the military "brigades" and "divisions," for these are in the field and ready to meet all comers.

Let not the reader imagine that my main scientific work has been the elucidation of the problems of cancer. Not at all! This portion of the work was a mere side-issue—an interlude. One, undoubtedly, of overwhelmingly momentous import for human interests, but one, regarded in the cold, clear light of science, which had to the investigator as such, and not as a fellow-creature, merely the import of furnishing a confirmation of the truth and validity of his conclusions in other and more fundamental directions. When I think of this there passes through my mind the picture of Carl Ernst von Baer, groping year in, year out, always groping to discover the laws of animal development. What was denied him has in the fullness of time been vouchsafed to one who, in admiration of his genius, followed humbly in his footsteps.

THE THEORY OF THE TOXIC ORIGIN OF PERNICIOUS ANEMIA.

By AUSTIN W. HOLLIS, M.D.,

NEW YORK,

ATTENDING PHYSICIAN TO ST. LUKE'S HOSPITAL;

AND

NORMAN E. DITMAN, A.M., M.D.

NEW YORK,

ASSISTANT ATTENDING PHYSICIAN TO ST. LUKE'S HOSPITAL, INSTRUCTOR IN PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, PATHOLOGIST TO SLOANE MATERNITY HOSPITAL, CLINICAL PATHOLOGIST TO ROOSEVELT HOSPITAL.

Pernicious anemia is defined by Sidney Coupland[1] as "a variety of primary anemia which arises insidiously, and is characterized by progressive diminution in the number, and changes in the form, of the red corpuscles of the blood, together with similar but generally less marked diminution in the amount of hemoglobin; which changes apparently depend upon undue hemolysis combined with inadequate compensatory hemogenesis—a condition which, in the majority of cases, passes more or less rapidly to a fatal termination, the progress being, in some cases, interrupted by periods of improvement, followed by relapse, but rarely resulting in permanent restoration to health, whatever the method of treatment." This definition, while very satisfactory in many ways, is not as concise and complete as that of Ewing[2], who calls attention to the changes in the bone marrow which have come to be considered characteristic of this condition.

To make complete the definition of that form of pernicious anemia which it has frequently been the custom to describe as "primary," "idiopathic," "cryptogenetic," or "essential," attention might well be called to evidence of a toxic element entering as a cause into the symptom complex.

Most authorities now exclude from the type of disease known as pernicious anemia those forms of anemia the causes of which have been well established, and reserve the term pernicious anemia, or, more frequently, primary progressive pernicious anemia, for that type long known as idiopathic or cryptogenetic. Strümpell[3] is among the most prominent of those who hold this view. On this basis would be excluded the grave anemias due to ankylostoma and bothriocephalus latus, repeated hemorrhages, and pregnancy. Wood[4] classifies these under the head of secondary anemias of the pernicious type, and considers them as more aggravated forms of the anemias to which group belong those due to chronic hemorrhage, tumors, lead poisoning, syphilis, malaria, typhoid fever, and chronic atrophy of the stomach. All of these differ in some way symptomatically from primary pernicious anemia.

That repeated hemorrhage is a cause of pernicious anemia was claimed by Habershon[5], Quincke[6], Schepelern[7], Finney[8], Greenhow[9], Stockman[10], and is still affirmed by some; but since the morphological changes in the blood and bone marrow have been required to establish completely the character of these anemias as pernicious very few have been seen. Ewing[2] states that he has never seen a case of pernicious anemia directly referable to hemorrhage.

Pregnancy as a cause of pernicious anemia is also fast becoming less important. Eichhorst[11] claimed that 35 per cent. of the cases published by him were caused by pregnancy. The genuineness of some of these cases may now be doubted; and at any rate the patients suffered from a variety of severe symptoms not at present regarded as belonging to the disease, so that Lazarus[12] classes many of them as examples of secondary anemia and exhaustion. Cases of progressive anemia accompanying pregnancy have gradually disappeared from recent literature, Ehrlich being able to find only one case of this description (Laache, Case 9)[13]. At the Sloane Maternity Hospital, from 1892 to 1899, Ewing saw no cases of anemia of the progressive pernicious type, and from 1902 to the present time none has been seen by the present pathologist of that institution.

That ankylostoma and bothriocephalus latus may of themselves give rise to a progressive pernicious anemia is possible; but the fact that the latter exists frequently in the intestinal canal without producing this result would imply a variation in virulence of the parasite, an increased susceptibility of the host, or a coexistence or symbiosis with some other organism in the intestinal tract. There remains then a group which to the present time has still been designated idiopathic or primary progressive pernicious anemia.

Addison[14] classed as idiopathic those cases where there had been no previous loss of blood, no exhausting diarrhea, no chlorosis, no purpura, and no renal, splenic, marantic, glandular, strumous, or malignant disease. Musser[15] cites as other occasional preexisting causes, great physical overexertion, exposure, great shock or fright. Stockman[10] suggests that repeated small capillary hemorrhages—chiefly internal—play an important rôle in the causation of idiopathic pernicious anemia, and also claims that as a result of anemia, fatty degeneration of the walls of the small blood-vessels occurs, giving rise to greater hemorrhage, which by increasing the anemia completes a vicious circle, terminating ultimately in the pernicious grade of anemia and death. Stockman's views, however, have never been widely accepted.

The infectious origin of pernicious anemia has been advanced by Klebs[16], who claimed to have found an organism—*Cercomonas globulus*—in the blood; by Frankenhauser[17], who found an organism which he identified as *Cercomonas navicula*, and by Petrone[18], who reported the isolation of leptothrix in several cases. The fact that pernicious anemia is more frequent in some countries than in others Strümpell[3] considered to be one argument for assuming that the disease is an infectious one.

It has been maintained that unfavorable hygienic surroundings and insufficient nourishment promote the development of the disease. In this connection

it is well to consider that when an individual obtains insufficient nourishment that nourishment is also liable to be poor in quality, thereby creating greater opportunity for the introduction into the intestinal canal by this means of deleterious bacterial and chemical agencies.

F. P. Henry[19], Stephen Mackenzie[20], and Rindfleisch[21] are advocates of the view that the essence of the disease is in defective hemogenesis, in consequence of which the red blood corpuscles are abnormally vulnerable. Such a case was cited by P. Grawitz[22] of general sarcomatosis of the bone marrow accompanied by typical changes in the blood. Litten[23] and Waldstein[24] presented two cases which were obscure and of doubtful diagnosis.

The hemogenetic theory of the origin of the disease, as suggested by the remarkable reversion of the bone marrow to its fetal condition, first observed by Pepper[25] and Cohnheim[26], is one which has been advocated by some with considerable vigor. The significance of these bone marrow changes has been materially affected by the recognition of the part played by hemolysis in the disease as well as by the fact that they are not invariably met with, nor differ in kind, if they do in degree, from the changes in the marrow which occur in anemia experimentally produced by bleeding. Whenever these marrow changes are met with side by side with the characteristic hemolytic features of pernicious anemia they are more likely to be of a secondary nature, indicating an effort on the part of the hemogenetic organs to repair the waste that is in progress elsewhere.

Osler[27] believes that to explain the hemolysis, attention must be called to the condition of faulty gastrointestinal digestion which is so commonly associated with these cases, and that poisonous materials are developed which, when absorbed, cause destruction of the corpuscles. In Coupland's[1] opinion also the hemolytic doctrine assumes the operation of a specific toxic agency; and it is interesting to note that those who have studied the degenerative changes in the spinal cord, which are apparently more common in pernicious anemia than might be supposed from the clinical phenomena, believe also that these changes are best explained by a toxic influence.

Schuman[28] advocates the theory of the toxic origin of pernicious anemia, but believes with Immermann[29], Quincke[30], Lichtheim[31], and Fr. Müller[32] that it is not an etiological entity, but only a symptom complex which is brought about by various causes.

To suggest further the toxic nature of the disease it is only necessary to consider briefly some of the more marked and constant symptoms. And here it may be cautioned that toxic symptoms are not necessarily the result of the activity of organisms within the blood stream or tissue spaces alone, but may result from absorption of the products of bacteria which are on the surface of the body or in the alimentary canal—the most familiar type of surface absorption occurring, of course, in the infection by the diphtheria bacillus.

A peculiarity of the disease is the occurrence of fever of an irregular type which, though not constant, sometimes rises to 102° or 103° in the evenings, and is followed by a morning remission. A characteristic is its intermittence with fluctuations under slight influences. Another condition which occurs with even greater regularity is the digestive disturbance, which of all factors appears to point most closely to the toxic and gastrointestinal side of the etiology. Not only are the earliest symptoms connected with the digestive tract in a considerable proportion of the cases, such as vomiting, diarrhea, or irregularities of digestion, and loathing of food, but many cases exhibit also definite changes in the gastric or intestinal mucosa.

The reports of Sandoz[33] were apparently the first to strengthen the impression that some of the most typical cases of pernicious anemia are of intestinal autotoxic origin, this observer finding that apparently genuine cases were sometimes cured by vigorous gastric lavage, enteroclysis, and the administration of intestinal antiseptics and laxatives. This observation has since been verified and the opinion has steadily grown that the most frequent, if not the essential, cause of progressive pernicious anemia is found in a peculiar toxemia of intestinal origin, with or without organic lesions of the mucosa. The evidence supporting this opinion has accumulated from many sides. The results of intestinal antiseptic treatment have steadily pointed in this direction. Signs of increased intestinal putrefaction have been noted in the excessive indicanuria of the disease, and in the presence of cadaverin and putrescin in the urine of certain cases (Hunter[35]).

Hunter's studies (1901) in this field were undoubtedly the most important experimental contribution to the etiology of the disease made up to that time. His conclusions were, briefly, that pernicious anemia was a specific clinical condition resulting from excessive hemolysis, occurring chiefly in the portal system and brought about by intestinal intoxication in which the products of growth of specific bacteria are probably concerned.

Along this line Herter, in a lecture before the Harvey Society, entitled "The Common Bacterial Infection of the Digestive Tract and the Intoxications Arising from Them," has recently demonstrated the more or less constant presence of certain forms of anaërobic bacteria in the contents of the large intestine. These bacteria are Gram positive in their staining capacity and are represented most frequently by the *Bacillus aërogenes capsulatus*. These bacteria are able to break down proteids into a form suitable for the use of other putrefactive bacteria, among which are the indol-forming organisms, indol being a substance which, as stated before, occurs quite uniformly in excess in pernicious anemia. The significance of the presence of this excess of indol was shown by Dr. Herter by the production of toxic symptoms in animals whose oxidizing capacity had been reduced by small injections of potassium cyanide, causing a condition of diminished oxidation which it is more than likely occurs in conditions of blood poverty.

These anaërobic organisms produce substances which are strongly hemolytic, so that it only has to be assumed that these substances pass through the intestinal wall more or less intact to have access with destructive effect to the blood of the portal system—where Hunter has found the greater part of the hemolysis to occur. But the observation of greatest practical value which Herter has made in this connection was obtained by the demonstration of the action of methylene blue, which changes to a colorless leucobase upon reduction. By this means he found that oxygen occurred in the intestinal canal as far down as the ileocecal valve, but no further. As these anaërobic bacteria are confined for their place of residence to regions free from oxygen, they must be limited to the large intestine where they are within reach of therapeutic measures directed from the lower end of the gastrointestinal canal; hence, the possibility which he affirmed of removing them by irrigation of or local applications in the colon.

Upon his suggestion two cases of undoubted per-

nicious anemia were treated in this way in the wards of St. Luke's Hospital in New York, and the results obtained in these cases by means of colon irrigation were sufficiently noteworthy to merit permanent record.

The first case occurred during the medical services of Drs. Hollis, Norrie, and Janeway, and the late Drs. Davis and Spalding. The second case occurred during the fall service of Dr. Austin W. Hollis.

The first case was that of a man twenty-nine years of age, a laborer, born in Ireland. When he first came under observation, December 23, 1902, he gave a history of having had for three years shortness of breath, swelling of the feet and about the eyes. He complained of headaches and dizziness in the morning, numbness of the legs, constipation, and progressive weakness. Soreness and pain in the abdomen had caused him considerable discomfort.

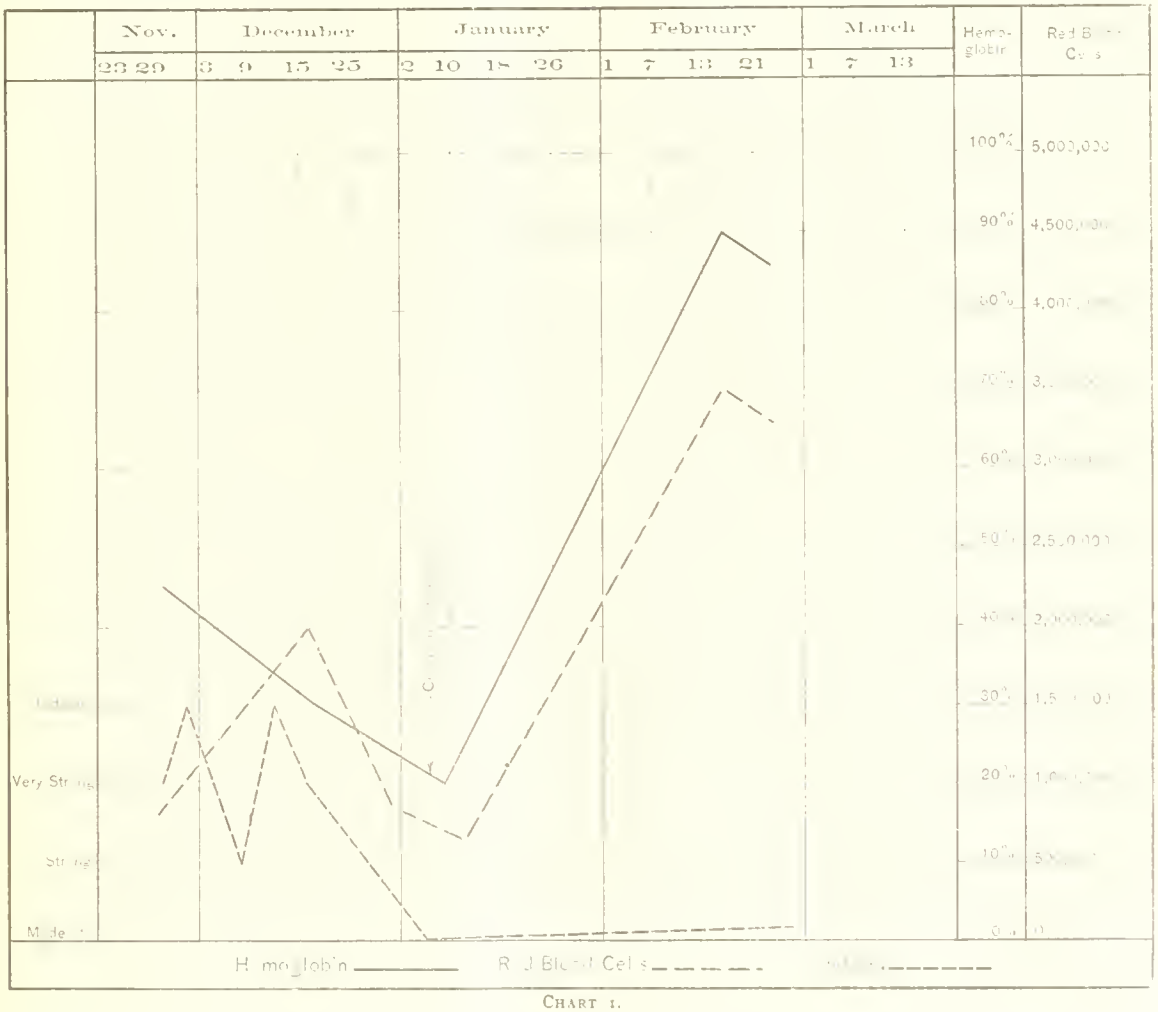

CHART 1.

His skin was pale, yellowish in color, and his tongue was slightly coated. His lungs were normal. A hemic murmur was heard over the heart. His feet and legs were edematous; knee jerks were not obtained. His physical examination otherwise showed nothing abnormal. The urine was normal.

At the time he was placed under observation his hemoglobin was 25 per cent.; red blood cells, 928,000. The differential leucocyte count showed 59 per cent. of polynuclears, 38 per cent. of lymphocytes, 2 per cent. of eosinophiles, and 1 per cent. of mast cells. Morphologically his blood was typical of pernicious anemia. A test meal showed an absence of free hydrochloric acid in the stomach. During the early part of his stay in the hospital his temperature occasionally rose as high as 101.6°. He was given arsenious acid and Blaud's laminoids upon admission, and these were kept up continuously, with lavage, and after February 2 atoxyl was given hypodermatically in doses of 25 minims.

The following table shows the course of the blood changes:

Dec.	27.	Hmglb.	25 per cent.	Red Blood Cells 928,000
Jan.	3.	"	27 "	" 1,612,000
Jan.	10.	"	22 "	" 1,310,000
Jan.		"	18 "	" 1,776,000
Feb.	2	"	20 "	" 828,000
Feb.	17.	"	20 "	" 1,080,000
Mar.	11.	"	30 "	" 1,202,000
Apr.	3.	"	30 "	" 1,696,000

There was moderate improvement at the time he left the hospital, but during each succeeding summer he was compelled to return for treatment, complaining of dyspnea, palpitation, dizziness, headache, and weakness. Each time his blood condition had deteriorated since the preceding stay in the hospital, although at one time his hemoglobin rose to 50 per cent. and the red blood cells to 2,372,000.

The gastrointestinal symptoms became more marked and during the year previous to the last term of treatment he suffered especially from constant morning vomiting, dizziness, headache, fever, weakness, and pain in the legs. A strong indican reaction was found in the urine. His medication had included from time to time Fowler's solution, iron, nux vomica, sodium cacodylate, and dilute hydrochloric acid.

The above symptoms were present on his admission to the hospital on November 23, 1905, and were accompanied by a hemoglobin percentage of 45, and 900,000 red blood cells. His condition was unimproved by the administration of arsenic and strychnine up to January 8, 1906. Irrigation of the colon

was then commenced, using once a day a double current of warm saline solution until the return flow was clear. Reference to the accompanying chart will show the almost immediate response to this measure with an ultimate rise in hemoglobin to 85 per cent. and in red blood cells to 3,400,000.

Since leaving the hospital this man has had daily colon irrigations, and eight months after his discharge from the hospital his hemoglobin was still 85 per cent. and the red blood cells 3,800,000. His health remained perfect.

Another case of a similar nature was that of a man aged fifty-three, a publisher by occupation, who, with the exception of habitual shortness of breath which prevented his taking any active exercise, had nothing in his previous history which could have any bearing on the disease. For a year previous to admission to the hospital he had been gradually losing energy and strength. This had been accompanied by a loss of twenty-five pounds in weight. The skin had become much pigmented. His appetite constantly decreased, and there was a good deal of distress after eating, with eructations of gas and frequent vomiting. Shortness of breath and headache became continuously more troublesome. A few days before admission weakness caused him to discontinue work and finally became so marked that walking was impossible. There had been slight fever (101°). His bowels were regular.

On admission his physical examination showed pallor and yellow tinge of skin; nutrition fair; tongue coated; pupils, pulse, lungs, liver, and abdomen normal. A hemic murmur was heard at the apex of the heart. The kidneys were not palpable, but the edge of the spleen—soft and thin—was just palpable below the free border of the ribs. Knee jerks were not obtained. Shortly after admission he suffered from pain in the legs, which was of about two weeks' duration.

On admission to the hospital his hemoglobin was 28 per cent., red blood cells 1,320,000, leucocytes 5,200. The differential leucocyte count showed 36 per cent. polynuclears, 64 per cent. lymphocytes. The red blood cells stained deeply, the central depression being very slight. Normoblasts and megaloblasts were present; poikilocytosis and polychromatophilia were marked. Indican was present in a trace in the urine and albumin was present to the extent of 10 per cent. by bulk.

His medication at first consisted of nux vomica and Fowler's solution, and dilute hydrochloric acid.

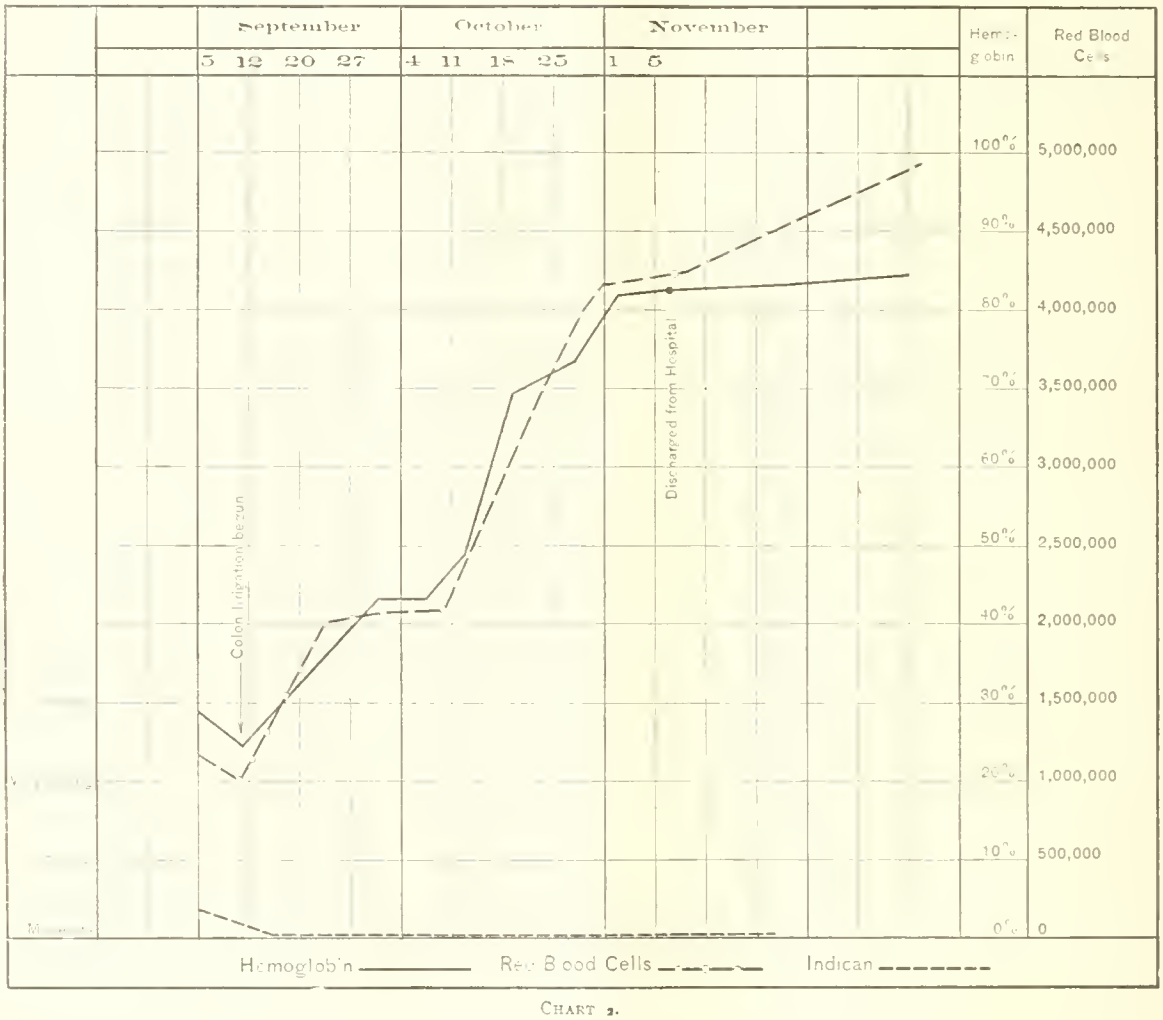

CHART 2.

On September 8, after slight diminution in the hemoglobin and red blood cells, colon irrigations were commenced. The trace of indican disappeared. The albumin was diminished to a faint trace in four days and disappeared in a week. Reference to the accompanying chart will show clearly the marked improvement in this man's blood condition.

On the 5th of November he left the hospital feeling perfectly well. One month later he had gained ten pounds in weight and his blood condition continued to improve as shown by the chart.

That these cases have been permently cured it is impossible at this time to say. It is evident, however, that since the introduction of the treatment by colon irrigation in these cases more marked improvement was obtained than by any other method employed. It is also evident that the fact that two

very severe cases of anemia of the pernicious type have been restored to perfect health and a normal blood condition by high colon irrigations, would seem to imply, for these cases at least, the absorption of some toxic substance from the bowel as a causative agent.

The practical difference between the old and more recent results is no more striking, however, than that between some of the older and newer theoretical conceptions upon which the therapy is based. This is very well illustrated by the fact that while in former times it was taught by some of the most prominent men of the time that the more food the patient could take the better, in the view of modern developments as emphasized by Herter, smaller amounts are better, especially of proteid food. For any excess of proteid food reaching the part of the intestinal canal occupied by the proteid splitting anaërobic bacteria of the lower bowel, simply furnishes material for subsequent decomposition into toxic and hemolytic substances as the result of bacterial activity.

The great value in the discovery that such a condition as pernicious anemia can be so benefited by removing intestinal bacterial matter lies in the fact that it emphasizes the possibility of attacking other obscure diseases on the same ground. The agency of bacteria in disease seems to be well appreciated when they occur in contact with the surface of the body, in the oral or genitourinary or respiratory cavities. Even the deleterious effect of the absorption of the products of the activity of nonpathogenic or saprophytic bacteria is appreciated when occurring within the uterus, to produce a sapremia. Yet few seem to appreciate what a great amount of absorption must occur where the area of absorption is as great as that of the intestinal mucosa, or what a diversity of chemical products, many the result of bacterial activity, present themselves for absorption. It is, however, of extreme importance to recognize this diversity of chemical products, many of which in conditions of health may not be toxic, but under conditions of slight impairment of the detoxicating or oxidizing action of the liver or intestinal mucosa, or when acting through long periods of time may be responsible for many of our unsolved symptom complexes of disease.

We take pleasure in expressing to Drs. A. D. Mittendorf, L. Hutton, and W. W. Herrick of the medical staff of St. Luke's Hospital, to Drs. F. Girard, C. Vail, and C. E. Lieb of the pathological staff of St. Luke's Hospital, and to the staff of Dr. Herter's laboratory, our appreciation of the assistance which they have rendered. To Drs. V. H. Norrie, T. C. Janeway, and the late Drs. G. A. Spalding and A. A. Davis we are indebted for the use of notes on the first case.

THE ELECTRIC PSYCHOMETER.

By FREDERICK PETERSON, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF PSYCHIATRY IN COLUMBIA UNIVERSITY; CONSULTING ALIENIST TO BELLEVUE HOSPITAL.

In Pflüger's *Archiv für Physiologie*, 1890, Prof. J. Tarchanoff published a paper on "Galvanic phenomena in the human skin in connection with irritation of the sensory organs, and in various forms of psychic activity." Like many discoveries of great importance, his remarkable work lay buried for years. Only lately has the full import of his experiments begun to be realized. They deserve a recapitulation here. The apparatus used was the minor galvanometer of Meissner and Meyerstein. The deviations of the mirror were noted by means of a telescope upon a scale three meters distant from the galvanometer. The scale was divided on each side of the zero point into 50 cm., and these again into millimeters. The galvanometer was so sensitive that the nerve-stream of a frog's sciatic nerve sufficed to deviate the mirror to such extent that all the divisions on the scale vanished from the visual field. Tubular unpolarizable electrodes of clay were brought into contact with the skin by means of hygroscopic cotton pads 10 to 15 cm. long, saturated with saline solution. The electrodes were applied at different times to various parts of the body, such as the hands and fingers, feet and toes, face, nose, ears, and back. The results obtained were as follows:

Light tickling of the face, ears, or soles of the feet with a camel's hair brush or a feather produced, after a latent period of one to three seconds, a deviation of the galvanometer to the extent of the whole 50 cm. of the scale. The same results were obtained by irritating the skin with a faradic brush, by applying hot and cold water, and by pricking with a needle. The other senses—hearing, smell, taste, and sight—responded in the same way on the

galvanometer scale when similarly irritated. The experimenter thus discovered that the irritations themselves were not necessary, but that their presentation to the imagination also sufficed to induce the same deviations of the mirror of the galvanometer. Furthermore, he found that the recollection of some fear, fright, or joy, in general any kind of strong *emotion*, produced the same result. The next point of interest brought out by Tarchanoff was that ordinary abstract mental exercise, such as multiplication, had no effect upon the galvanometer, unless accompanied by exertion. He also found that the emotion of expectation or anticipation deflected the galvanometer. Tarchanoff explained the phenomenon observed as due to a secretory galvanic stream connected with the sweat-glands. He was probably unaware himself of the extraordinary value of his briefly described piece of work.

His report remained unnoticed for seven years, until Sticker (*Wiener klinische Rundschau*, 1897, Nos. 30-31) again brought the subject into medical literature, if not to the attention of medical men. He repeated the experiments of Tarchanoff, and came to the conclusion that the capillary system of blood-vessels was a factor in the perturbations of the galvanic current, by changing the conditions of resistance. He opposed Tarchanoff's idea of a centripetal excitation of a secretory stream, because he found that the same deviations in current were to be observed when the electrodes were applied to anesthetic and analgesic areas (functional or organic).

Five years more passed before this interesting topic again appeared in literature. Sommer of Giessen (*Beiträge zur psychiatrischen Klinik*, 1902, p. 157) made experiments in the same direction, but seems to have failed altogether to grasp the really important feature of the situation, losing himself in details of a physical character. At the same time he arrived at the erroneous conclusion that, except for a reaction on tickling, no psychic influence on the current was to be established with certainty. He observed fluctuations which he ascribed to changes in contact between skin and electrodes, and to changes in resistance of the skin. Any apparent psychic influences he thought due to involuntary muscular contractions inducing increased pressure on the electrodes. He therefore missed the one essential point.

About two years ago E. K. Müller, an electrical engineer at Zurich, read a paper before the Swiss Society of Natural Sciences, Medical Section (1904), on "The Influence of Psychic and Physiological Phenomena Upon the Electrical Conductivity of the Human Body." Happening to make certain experiments upon himself in relation to the resistance of the human body in the alternating magnetic field, he rediscovered the extraordinary variability of the mirror-galvanometer under psychic or nervous conditions, as established by Tarchanoff fourteen years before. Mr. Müller then induced Dr. O. Veraguth, a neurologist of Zurich, to experiment on the same lines. Veraguth gave the name "galvanic psychophysical reflex" to the phenomenon, and he published the results of his researches in the *Archives de Psychologie* (Geneva), in August, 1906. Veraguth employed the Deprez-d'Arsonval mirror galvanometer, nickel-plated brass cylinders for electrodes, a feeble current, a horizontal glass scale on which a light reflected from the mirror registered its movements, and an apparatus for photographic registration of the curve. Veraguth corroborated the findings of Tarchanoff. One or two of his experiments are especially striking. If the individual under observation is read to, deviation is noted when passages of particular interest are reached, that is, when accompanied by any emotional tone. Or, if a series of unselected words is pronounced, a test suggested to him by Jung of Zurich, the words associated with an emotional complex produce an effect upon the galvanometer, whereas others without emotional tone have no effect. Veraguth concludes from his studies that only such irritations as are connected with sufficiently intense and actual emotional tone produce a galvanometric deflection. He states in his report above mentioned that he is not yet in a position to explain the phenomenon, but if it is to be explained by simple change in resistance, then it presents manifold contradictions to our present conceptions of the resistance of the human body. He felt it not to be due to changes in the quantity of blood in the hands of the individual experimented upon, for the phenomenon occurs whether the hands be emptied of blood by an Esmarch bandage, or overfilled with blood by artificial venous stasis. Veraguth excludes the participation of perspiration in the effects, for the results he found to be similar after drying the hands with formalin.

In the Psychiatric Clinic at Zurich, under the direction of Prof. Bleuler, Dr. Jung has of late been studying the relation of the galvanometric deviations to psychic processes, and in conjunction with Dr. Jung, Dr. L. Binswanger has been experimenting upon the physical and physiological problems connected therewith. In a forthcoming number of *The Journal of Abnormal Psychology* of Boston, Dr. Jung has an article upon association experiments in which he employed the galvanometer, and the apparatus and curves obtained are therein illustrated. Dr. Binswanger's paper is not yet published. Both of these gentlemen placed at my disposition all of their own work and conclusions, as well as the apparatus of the laboratory, and Dr. Jung and myself have gone over together many experiments with the instrument in normal individuals and in cases of dementia præcox, while I have reported with both of them some of the physical and physiological experiments. Dr. Jung and I are now using the galvanometer in these cases, together with Morey's pneumograph and reaction time apparatus for kymographic curves with various irritations, both sensory (pricking, noises, and the like) and psychic (series of words and questions which are either indifferent or calculated to induce emotions or arouse emotional reflexes). This work involves so much study and detail that it will be some time before it is published.

As far as the physical side of these galvanic reactions is concerned, the problem cannot be said to be solved, but Drs. Jung and Binswanger have certainly excluded some of the alleged causes, viz., muscular contractions and variations in blood supply, and their conclusion so far is that the cause is probably a variation in resistance, depending upon changes in the amount of secretion in the sweat-glands. They consider that the formalin experiments are not sufficiently certain to exclude the perspiration theory.

The apparatus we are using is a Deprez-d'Arsonval mirror galvanometer; and a horizontal glass scale (made in Zurich) placed about one meter from the galvanometer (divided into centimeters and millimeters), to which a lamp is attached. The light shines upon the mirror, and is reflected back upon the scale, on which the ray of light travels to and fro like a magic finger, marking the fluctua-

tions in the organism of the individual experimented upon. We usually put the galvanometer into circuit with one or two Bunsen cells and a rheostat to reduce the current if necessary, the patient's hands making contact upon copper plates on clasping nickel-plated brass electrodes. Sometimes no cells at all are used, but the patient places one hand upon a zinc plate and the other upon a carbon plate, these plates with the warm, moist hand sufficing to produce a current. But like results may be obtained simply with monopolizable electrodes as established by Tarchanoff and corroborated by Jung and Binswanger (with another species of galvanometer). By an ingenious mechanism devised by Dr. Jung, the movements of the finger of light upon the scale may be registered in curves on the drum of the kymograph. The manner of contact with the body makes no particular difference in the phenomena; whether in the manner just described, or by water electrodes, or whether by thimbles placed upon the fingers and connected with the theophores.

Now, I am going farther than my conservative Swiss friends, in proposing the name "electric psychometer" for this apparatus, but it is a name that I feel sure, from my own observations, is warranted, and that it is a remarkable adjunct to work in normal and morbid psychology is not only already assured, but will ere long be firmly established. One is, in fact, overwhelmed with astonishment at its manifestations, as this ray of light glides to and fro in response to the emotional changes going on within an organism.

There are minor oscillations, which practice and observation exclude, due to the usual familiar factors which modify resistance, such as hot and cold, and dry and moist skin, varying surface of contact, and varying pressure, but these are, as stated, minor movements, and do not interfere, when understood, with the extraordinary deflections in connection with the emotions. These emotions must be actual and real. The emotion of expectant attention or anticipation (as in the threat of a needle-prick or apprehension of a noise) has a voluntary influence on the psychometer. There is usually a latent period of one or two seconds before the deviation begins, after the irritation has occurred, but the latent period is reduced by the intensity of the emotion aroused.

It is almost like sorcery to observe the behavior of the instrument with a series of words, some purposely chosen to be emotionally indifferent and others to strike some emotional complex deep in the soul of the individual experimented upon. The patient is required to respond to any word uttered with the first word that comes into his consciousness. Indifferent words produce no effect upon the finger of light in the psychometer, but words associated with an emotional complex send the light along the scale for a distance of one centimeter up to six or eight or more, in proportion to the intensity and actuality of the emotion aroused.

Using these series of words is like fishing. Each word is bait on a hook thrown into the sea of the unconscious, and the species of fish that likes the bait is immediately caught and brought to the surface. This method of study of associations in the mind of man, so effectually carried out by Jung before the discovery of this new instrument of precision, is now doubly efficient in that the emotional value of each word may now be *seen* and accurately recorded.

I have not observed anything thus far in my *Studienreise* that has interested me quite so much, and I felt that I should at once place the matter before my colleagues as a new field for their research, a new avenue by which to approach the secrets of the nervous system.

A FEW REMARKS ON MEDICAL EXPERT TESTIMONY.*

By GEORGE FRANKLIN SHIELS, M.D., C.M., F.R.C.S.E., L.R.C.P., ETC.,

NEW YORK.

PROBABLY there is no subject in the medical curriculum which is so much neglected as medical jurisprudence, and no branch of it so little considered as that which deals with medical evidence. As a result the graduate begins practice with practically no knowledge in this direction, and, if he be lucky, may go through life without being placed in a position to regret his lack of learning; on the other hand, he may at any moment be called into court as an expert witness, and in the hands of a clever lawyer may be made the object of ridicule. Remembering this, it would seem that an occasional paper on some branch of the subject is not amiss, and so I shall ask you to bear with me while, out of the many, I try to point out a few of what seem to me important phases of the question. This I will do under the following headings:

(A) Compensation of the medical expert.

(B) Points referring to the attitude and rights of the doctor while on the witness stand.

(C) Especial points in trials involving the question of insanity.

(D) The value of medical expert testimony as now introduced.

Before going further it will be necessary to make clear the difference between a witness, as to fact, and an expert witness, since the laws which govern these classes are widely different.

A witness as to the fact is one who sees, hears, or knows either actual facts connected with the case at issue, or facts from which legal inferences applicable to the case may be drawn. This witness, whether ignorant or learned, poor or rich, young or old, must give evidence when called upon, and should he refuse to answer questions which the court rules proper to be answered, he is liable to be punished for contempt of court.

An expert witness is one who, through especial study or experience, is particularly instructed in some art or trade, and may give his opinions on questions of science or skill relating to such art or trade.

Now, since every business or employment which has a particular class devoted to its pursuit is an art or trade in the legal sense, it can be readily understood that a medical man, when called upon to give his opinion evidence connected with his profession, is an expert witness.

(*A*) *Compensation of the Medical Expert.* In civil actions the question of compensation rarely arises since the attorneys usually call upon the witness and make a definite business arrangement with him regarding his fee. In criminal procedures compensation is a common cause of misunderstanding and trouble, and in such cases I strongly advise medical men to demand their fee before going on the witness stand and giving their opinion evidence. In spite of the fact that the common law has established the understanding that the professional opinion of a physician is to be regarded in the light of property, and that the scientific or expert witness must be paid just as the merchant is paid for

*Read at a meeting of the Bridgeport, Conn., Medical Association, December, 1906

his wares or the farmer for his crops, still in many States he is offered the common witness fee, and is told he must be satisfied with that or nothing. Where the doctor has contested the matter it has been found that the court opinions for and against extra compensation are about equally balanced, and that should he claim an exception exists exempting him from the general rule which requires all witnesses, on the payment of the fee allowed by statute, to testify as to matters within their knowledge, then the burden is on him to establish the exception.

Another and interesting phase of the subject of compensation, and one which often comes up, is as follows: A doctor sees, for instance, an assault in which a man's leg is broken, and is subpœnaed to give evidence as to what he saw. During his examination the attorney directs his questions to obtain opinion evidence concerning the natures, causes, and effects of fractures. In this case there is no question as to the witness having to testify as to what he saw, but he can and should positively refuse to give his opinions relative to fractures unless he receives especial compensation as an expert witness. This holds equally good in civil actions, such as street car accidents, etc.

(*B*) *Points Referring to the Attitude and Rights of the Doctor while on the Witness Stand.*—While we know that there are many physicians and surgeons who, through association with railroads, mills, accident insurance companies, etc., are cool and self-possessed while on the witness stand, still the average practitioner looks on such an experience with a certain feeling of dread; hence I feel that I may draw attention to a few points which may be of use in this regard.

(1) Let the witness at all times remember that he is, by virtue of his diploma, an expert opinion witness, that he is in court to express his own opinions irrespective of any author or authority to the contrary.

The tendency on the part of attorneys is to borrow or buy numerous supposedly authoritative works, and to study them diligently over night. They come into court full of what they conceive to be medical knowledge, but, as a rule, knowing less than before they burned the midnight oil in cramming up for the trial. Knowing this, a doctor need not fear their attacks, and by maintaining a cool and quiet demeanor he will in the large majority of cases come out right in the end.

(2) Let him always keep in mind that he has an inalienable right to explain any answer he may give, even though it be simply "yes" or "no." By keeping this in mind he will often be able to set at naught the efforts of an attorney to make him stultify himself.

(3) Let him at all times be ready to frankly acknowledge ignorance should he be ignorant on any point. Anything like evasion will at once be noticed by the attorney, who will do his best to show ignorance, and will enlarge on it to the discomfiture of the witness. This he will do, even though the subject of the question be trivial, irrelevant, and immaterial since his object is to belittle the doctor in the minds of the jury, and thus lessen the value of his other testimony.

(4) Let him always, when asked, freely acknowledge that he is paid for his services. It is an axiomatic fact that the laborer is worthy of his hire, and, though the lawyer always tries to show that by being paid a witness is biased, still a frank statement that one is paid for his time and skill will never weaken a man's status before any court.

(7) He should avoid as far as possible the use of technical terms, and, if it is necessary to use them, explain their meaning in plain English.

(9) Let the witness always remember that should he feel that an attorney has gone too far, and has become insulting, he may turn to the judge and request his protection against such insult. In the experience of the writer this has never failed to have an immediate effect.

(10) Let the witness go on the stand with the absolute promise to himself that he will not lose his temper, for the lawyer takes great delight in trying it sorely.

(11) Let him never permit himself to becoeme so biased that he will allow himself to avoid an honest answer to any question, even though the question is asked by the attorney on the opposite side, and may seem to be against the best interests of his own side.

(12) On answering the usual hypothetical question asked by the lawyers, let him thoroughly understand it, and, should it be needful, let him explain his answer should he think that such answer places him in a false light before the court.

(13) No medical man should ever allow himself to be drawn into a trial where he is in doubt as to the real merit of the case from a medical or surgical point of view.

(C) Especial Points in Cases Involving the Question of Insanity.—My remarks under this heading are directed to the question of the criminal responsibility of the insane. It would take volumes to go into the discussion of the subject of insanity in all its medicolegal aspects.

In trials where the question of soundness of mind is the issue a complicated condition of affairs generally results, and, while the jurors are the final judges, the physician is always called to aid them by the expression of his opinion, and by giving them the benefit of his experience and study. The reason for these complications is not far to seek since the view point of law and medicine is entirely different.

No well-balanced medical man would attempt to unqualifiedly define insanity. The very definition that it is a disease of the mind naturally leads to the question, "What is the mind?" And even such an authority as Herbert Spencer frankly states that he does not know. In order to be able to definitely state the nature of insanity, it would be first necessary to define the meaning of the word sane. This is practically impossible, since it is a conventional and approximate term applied by use and custom to a class of individuals who think and act in a certain way regarding themselves, and toward society at large. While a distinct departure from this standard would easily be established as insane, who would venture to draw a distinct line between sanity and eccentricity, or between eccentricity and insanity? We all can say "this is day," or "this is night." Who can say "here day ends," "here night begins." There is the twilight, which is neither day nor night, but in part both, and which cannot be described or defined. Oftentimes so it is with the change from sanity to insanity. Gentlemen in our profession, there is no such thing as an absolute definition of insanity. Each case must be taken and studied as a separate entity, and frequently the most careful study leaves the physician in doubt.

On the other hand, it would seem necessary to have a legal definition of insanity, since the insane cannot be held responsible for their acts, and since insanity is very frequently used as a plea in the defense of prisoners who have committed criminal acts.

Out of the multitudinous efforts to reach a satis-

factory understanding, there has been evolved the following postulates: (1) A sane individual can distinguish between "right" and "wrong" in the concrete case; (2) he is possessed of will power adequate to control his impulses, and to control them in the light of that knowledge of right and wrong. The law presumes a man to be sane according to this standard.

From these postulates the law has constructed a definition of insanity, which holds good in most of our States, and which is as follows: "A man or woman is insane who does not know the difference between right and wrong in regard to any specific particular act, and who further does not know the consequences of committing such act." The question must be relative to the particular act done, and the accused's knowledge of the situation in which he did it. Did he know it was wrong at that moment? Was he impressed with the consciousness of guilt and the fear of punishment? If he did not he is insane according to the law.

It is easy to see from what I have said that no physician could possibly agree with this legal definition of insanity and that were it applied to a large proportion of the inmates of our State asylums, they must be held to be sane. For instance, witness the insane patient who knows that it is wrong, and against the laws of the institution, to smoke in the wards, who knows that he will be punished if he does it, and who still, with great cunning and forethought, plans his smoking to escape detection by the officials of the hospital.

In closing this portion of my paper, I wish emphatically to advise the medical witness to refuse at all times even to attempt to give a general definition of insanity.

As to the legal definition, it is purely a matter of personal opinion whether he approves or disapproves of it. No matter what the doctor may think to the contrary, the legal definition stands as the law, and is not question for argument. The jury will decide whether the case at issue fits it.

(*D*) *The Value of Medical Expert Testimony as Now Introduced.*—Expert testimony is no more conclusive to the jury than the testimony of witnesses as to fact, and no matter how learnedly a doctor may descant upon a technical point, the jury has a perfect right to accept or reject any or all of the evidence given by such opinion witnesses. However, judges will as a rule instruct juries that expert evidence, if from a high source, and if delivered without bias and with proper caution, must be given great weight. For my own part, I beg to say that medical expert testimony as now introduced can, in the large majority of cases, be of little value, and for these reasons: There are few men who, when employed in the interest of an individual or a corporation, can resist the tendency toward bias, and I have actually seen cases where such witnesses have sworn to opinions to which in their calmer moments, when free from bias, they could not have given their support. Again, it is almost laughable to hear the flat contradictions which occur where medical experts are put on the stand by contesting parties, and it must lead the intelligent mind to formulate a very poor opinion of our profession. Certainly were I on a jury which had to consider such evidence, I should give it little or no weight. Further, since to be a doctor is a sufficient ground to establish a man as a medical expert witness, one can easily see how a graduate of a two-year irregular college, with a glib tongue and a positive and convincing manner, can, by contradicting it, cause a jury to practically throw out the opinion evidence of a weighty authority who is not blessed with the ability to express himself with force and clearness.

But, gentlemen, expert medical evidence could be made of the greatest value in forwarding justice were it properly introduced. May I suggest two perfectly feasible plans: (1) Let the attorneys of each side select two experts, and let the four thus chosen agree on a fifth. These five men could, after careful deliberation, bring in a full and useful report on any technical points placed before them. Or (2) leave the matter entirely in the hands of the court, who could call one or a dozen medical men to elucidate, with absolute freedom from bias, any technical points which might arise in a trial. I incline strongly to favor the court having the control, since it would entirely do away with the possibility of partisanship, provided always that the court is what it should be—learned, dignified, and absolutely impersonal. Under this rule the very best men in the ranks of the medical profession would always be ready and glad to give their services, instead of shunning the courts on account of the false position in which they are so frequently placed by the warring attorneys.

Lawyers may urge that my plan places too much power in the hands of the judge. I do not think so. The more responsibility and power vested in the judicial office the more readily will the man sink his own personality and rise to a full appreciation of the grave, dignified, honorable nature of the position which the people have called upon him to occupy, and the confidence placed in him will be a sacred and inviolable trust which nothing could cause him for a moment to forget.

VARICOSE VEINS OF THE LOWER EXTREMITIES AND THEIR TREATMENT.*

By P. T. O'CONNOR, M.D.,

WATERBURY, CONN.

In order to discuss intelligently the surgical treatment of varicose veins of the lower extremities, we must admit that all treatment, in order to rise above the plane of mere empiricism, must rest upon a threefold conception: (1) of the etiology of the disease, (2) of the pathology of the disease, and, finally, (3) of its natural tendency, or a foreknowledge by which a cure may be accomplished. These principles will apply with special pertinency to the treatment of varices, and before we can expect to treat the disease rationally we must first know its cause and then its inevitable course.

Without going into unnecessary detail, it will suffice to know that the causes of varicose veins may be divided into predisposing and exciting. The valves of the veins play an important part in the etiology of varix, and in this relation their great variability in number, position, and development is to be noted. In the internal saphenous vein, the valves vary in number from seven to twenty. One of these valves is situated just at the termination of the vein and another at the outer side of the cribriform fascia, but both of these valves are sometimes imperfect or absent. The valves of the external saphenous vein vary in number from nine to thirteen. In relation to the backward pressure in the saphenous vein, it is to be noted that the femoral vein, above the entrance of the saphenous, and the external iliac vein are frequently, and the superior vena cava constantly, devoid of valves. Soboroff has demonstrated that the veins vary in thickness

*Read before the New Haven County Medical Association, October 25, 1906.

and strength in different individuals from birth. When a vein with weak walls has few valves, the tendency to varix is increased; and when the vein wall is of average strength, if the valves in the vein are few in number, this condition alone may act as a predisposing cause. That is, with few valves, each segment of the vein between the valves will have to support a longer column of blood than would be the case if the valves were more numerous and nearer together. In consequence the strain will be greater upon both the valves and the vein walls, and should an exciting cause occur, the veins or valves would have to yield to the increased blood pressure. These factors of inequality in vein strength and inequality in the number of valves play an important part in the asymmetry of varix. It is also important to remember that any exciting causes which produce increased intravenous pressure tend to the production of varicose veins. The affection is seldom seen in youth, but is very common in middle and advanced age. According to Billroth, women are more apt to suffer from varicose veins than men. The disease in this class of patients arises from interference with the free return of venous blood from the obstruction offered by physiological or pathological enlargement of the uterus. The venous obstruction caused by tight garters is also a factor in the production of this lesion.

Occupation plays an important part in the production of varicose veins. Those whose occupation keeps them habitually upon their feet are apt to suffer. There also seems to be an hereditary influence which predisposes to this condition. Members of the same family, through several generations, will often suffer from varicose veins. Gravity increases the intravenous pressure, and its effects are most marked at the lower end of the blood column.

The first pathological condition in varix is the permanent localized dilatation of a vein. Veins which are so affected are said to be varicosed, and present an enlarged, elongated, tortuous, and knotty condition. The superficial veins of the lower extremity are those most commonly involved, the internal saphenous and its branches being most often affected. The deep veins are usually free from the disease, though Verneuil says that varix is as common in the deep-seated as in the superficial vessels (Bryant). Recent observers, however, do not entertain this view, particularly Borden, who claims that when the deep veins are involved they are usually secondary to superficial varicosities, but occasionally the communicating branches between the deep and superficial veins may be affected, and a varix is not infrequently observed at the point. The disease begins with the slow dilatation of a vein. It is not only enlarged transversely, but is also elongated, and as the ends of the vein are fixed points, the increase in length causes it to become very tortuous. In other cases, dilatation is most marked, and elongation does not occur to any great extent. The coats of the involved veins are morbidly thickened, the endothelial coat presents longitudinal striæ, and in long-standing cases atheromatous changes or calcification may sometimes be observed. The external coat is also very much thickened by reason of connective-tissue infiltration and inflammatory new-formation, to which the name periphlebitis is attached. The valves are shortened, or often disappear, and become insufficient to support the column of blood. As a result of increased exudation of serum in the perivascular and lymph spaces, the lymph channels are unable to carry away the excessive exudate and edema occurs in the immediate neighborhood of the varix. From these observations it will be seen that a varix may arise from the local insufficiency of a vein, or from an excessive blood pressure within a vein, or from a combination of these factors. It will also be seen that a varix is at the beginning generally localized and confined to one or several parts of a vein; that it is usually a progressive disease, and that the disease condition is apt to continue or extend until the whole vein and its branches are involved. These factors are of importance from the standpoint of treatment, in that, considering the tendency of a varix to increase, the necessity for interference in the early stages of the trouble becomes evident. Through swelling of the limb, pain, soreness, and a feeling of fatigue in the affected member, a small varix will frequently produce great discomfort and almost incapacitate one for manual labor. Inflammation and thrombosis are not infrequently complications of varices. Ulcers occurring in connection with varicose veins are often spoken of as varicose ulcers, but the relation of the ulcers to the varices seems to be rather accidental than casual. One of the greatest dangers to the patient suffering from varicose veins is the danger of sudden rupture which usually follows a scratch or a bruise over a thinned portion of a vein. The bleeding is profuse, and unless checked may cause a fatal termination.

In view of the foregoing clinical facts, what, may we ask, would be the indication for treatment? The subject, however, seems to resolve itself into two important questions: Shall we resort to palliative treatment, which offers temporary relief only; or shall we have recourse to operative measures by which a permanent cure can be obtained? We believe the latter plan of treatment is the only one worthy of our consideration, and the choice by election regarding the operative procedure will depend entirely upon the form, character, and duration of the varicosities involved. It is generally conceded by the profession that the lower extremity is more accessible to thorough manipulation than any other portion of the body. Therefore we are sometimes at a loss to comprehend why patients thus afflicted are neglected in general practice, unless it be out of respect to tradition, or the dread of sepsis. Surgical interference in varix was so disastrous in preantiseptic days that the traditional timidity that still obtains to a certain extent and has been a potent factor in preventing the more general use of rational measures, is in part accounted for. With the safeguards of modern aseptic methods this attitude should no longer be maintained. In fact, the milder forms of the disease, in which palliative treatment is usually the only measure thought of, are frequently the very ones in which operative treatment should be adopted. The course of the disease is so generally progressive that this characteristic of the trouble is one of the most important reasons for early surgical interference. By doing away with the trouble before the entire main trunk and its branches have become involved, extension of the disease may be prevented, as well as the necessity for a large operation in the future.

While with Dr. Arpad G. Gerster at Mount Sinai Hospital in 1896, the writer had a favorable opportunity to observe a large number of cases of this nature and he arrived at the conclusion that it was not alone the greater degree of surgical skill and dexterity that determined one's success in the management of such cases, but what appeared to be a factor of equal importance in this, as in many other operative procedures, was the aseptic precaution necessary to be carried out before, during, and after manipulation. Asepsis, once mastered, soon be-

comes a matter of routine, and is the key to rational measures, which will invariably lead to successful results.

Of course, in preantiseptic days, the surgical manipulation in operating on varix was not infrequently followed by septic infection, with the resulting endophlebitis extending along the vein and causing inflammatory changes in the intima, which led to thrombosis and obliterative phlebitis. In aseptic ligation the changes ought not to occur, and the obliteration of the vein can be accomplished only by placing the ligatures so close together—not more than two inches apart—as entirely to obliterate the vein as a blood channel. The operation of multiple ligation is a simple one, only requiring care in regard to the asepsis and in so placing the ligatures as not to include the nerves which accompany the vessel. The writer has performed this operation in a number of cases with gratifying results, and believes it ought to be resorted to in cases of localized varices in which the more elaborate measures of partial or complete excision are contraindicated, or where the patient will not submit to an operation of magnitude.

In a certain number of cases, with involvement of the main trunk of the vena saphena magna, the greatest dilatation is always situated just above the valves. The latter are often destroyed or rendered incompetent and cause the vessel to support a column of blood extending from the lowest dilatation to the heart. In such cases, high ligation or the operation of Remi and Trendelenburg may be resorted to. Ligaturing the vessel relieves it of the pressure of the column of blood below the point of tying, and permits the restoration of vascular tone. In doing this operation, G. Perthes recommends excision of a short portion of the vein between two ligatures, thereby preventing reestablishment of the patency of the vessel, for Minkewitsch has shown that no restoration of a vessel can occur after a portion of it has been excised. Most modern surgeons, by reason of the etiology and pathology of varix, do not consider Shede's operation a proper procedure, as the damage it does to the nerves and the uncertainty of cure make it of doubtful propriety in any case.

The surgeon has his choice of a number of operative procedures. In certain selected cases he must have recourse to Phelps's operation, partial excision, or to the still more radical method of complete excision. The writer first performed the latter operation six years ago in the case of a woman 35 years old, who was rendered almost a practical invalid by reason of an aggravated form of varices of both the internal and external saphenous veins, which communicated with the deeper vessels, and which was made more complicated by a large ulcer on the interior surface of the leg, a condition which existed over a period of eight years. The patient had submitted to all manner and forms of palliative treatment and was informed by reputable physicians that her condition could not be cured. The internal and external saphenous veins were dissected out, ligated, and excised. The patient made an uneventful recovery. Shortly afterward she secured a position which necessitated considerable activity on her part and has continued to perform her duties without the least return of her former trouble.

Influence of Chocolate and Coffee on Uric Acid.—René Fauvel declares that the methylxanthins (theobromine and caffeine) of chocolate and coffee distinctly increase the urinary purins, but not uric acid, and they prevent its precipitation by acids. Their influence, especially that of theobromine, is far more favorable to the organism than that of the purins of meat and of the leguminous vegetables which give a large proportion of uric acid which is easily precipitated. These conclusions concern alone the actions of theobromine and caffeine on uric acid and the urinary purins and not their influence on digestion, circulation, or the nervous system.—*Gazette des Hôpitaux Civils et Militaires.*

Early Electrical Treatment of Acute Poliomyelitis of Children.—Ezio Luisada has treated 170 cases of acute poliomyelitis of children in the hospital at Florence, and states that the results of treatment are much better when the electrical applications are begun as soon as the fever has passed over. He believes that it is a distinct disadvantage to wait as long as is commonly done before beginning electrical treatment. Patients are rarely seen in the stage of invasion, and the diagnosis is difficult before the paralysis appears, which is after the fall of temperature. The period of regression begins in from one to three weeks. When the inflammation lessens, and the hyperemia of the spinal cord, with its compression and injury has passed away an electrical examination should be made, and mild applications of electricity begun. With the indifferent electrode on the brachial plexus or the lumbosacral region the current does not pass near the inflamed spinal cord, and no injury can be done to it. Children in whom the treatment is begun in from fifteen to thirty days from the beginning of the illness, recover more quickly and more thoroughly than those in whom the applications are delayed. The progress of the patient is affected by the season of the year, spring being most favorable. Cold weather with its poor circulation prevents repair. In very young children the nervous centers are not yet developed, and the destruction of certain portions may be replaced by new development of other regions. If the muscles and peripheral nerves be kept in good condition by electricity, they will be ready to respond when the centers are regenerated.—*Annali di Elettricità Medica e Terapia Fisica.*

Murphy Button.—A procedure that is used by many surgeons in order to shorten the time required for securing the Murphy button in position is referred to by Gelpke. Murphy's original direction was to make a purse-string suture and to incise the center of the circle so outlined for the introduction of the half of the button. Instead of this, the slit through the gut may be made first, the button slipped into place, and then fastened by a single interrupted suture at each side. To prevent the button from dropping into the stomach instead of into the intestine in gastroenterostomy, a silk thread four inches long and attached to a small metallic ball may be tied to the intestinal half of the button.—*Correspondenz-Blatt für Schweizer Aerzte.*

Scorbutic Symptoms Caused by the Bacillus of Eberth.—Giovanni Arpa Auverny describes a rare hemorrhagic form of typhoid, in which all the symptoms were much more suggestive of scurvy than of typhoid fever. The fever had not the typical curve of typhoid, rising to 40° for five days, and then remaining at 38° for five days, after which, accompanied by a hemorrhagic eruption over the entire body, it rose again to 40°, and remained at about that until the patient's death on the eighteenth day of the disease. There were no symptoms connected with the digestive tract, but after death there were found multiple ulcerations of Peyer's patches. There were at no time hemorrhages into the intestine, but there was epistaxis, swelling, sponginess and bleeding of the gums, and hemorrhage from vagina and bladder. Examination of the blood showed the presence of short bacilli, which proved to be the bacilli of Eberth. The condition was one of scurvy caused by the typhoid bacillus. The author believes that the bacillus exerted its influence mechanically, and by its presence in the blood, rather than by its poisonous products.—*La Riforma Medica.*

MEDICAL RECORD.

New York, February 2, 1907.

FORMIC ACID IN DIPHTHERIA.

THE signal success which has marked the introduction and employment of diphtheria antitoxin has led to a feeling of such general satisfaction that very little effort has been made in recent years to improve or add to present methods of treatment. It must be admitted that the mortality has been reduced within a comparatively short period to a remarkable extent: and yet the disease works much havoc, for if not immediately fatal, the after-effects in many instances are such as to cause much alarm. Toxemia is the word which will best define the cause of these sequelæ as well as that of death itself, and it is in the treatment of this condition that enlightenment is very greatly desired. It would appear that a sufficiently powerful dose of antitoxin administered at an early stage of the infection, so that the toxins could be antidoted before the tissues would be devitalized or degenerated, would comprise the proper conception of perfect treatment. Such is probably the case, but so varied is the individual reristance that we have no means of knowing what the exact antitoxic gauge may be in any given case.

The three main complications which are met with in the course of the disease are cardiac failure, paralysis, and renal involvement, of which the more important are paralysis and cardiac failure. Apart from the local treatment and the administration of antitoxin, the method hitherto employed has been one of stimulation, mainly by strychnine, strophanthus, and digitalis. The main action of these is to raise the blood pressure by increasing the cardiac force, contracting the arteries, and in lesser degree stimulating the vasomotor centers in the medulla and cord. It has been shown that these drugs are not ideal, for they increase the amount of work required of a heart which already manifests a tendency to degeneration. As a substitute for these measures, Croom (*Edinburgh Medical Journal*, October, 1906) calls attention to the value of formic acid and the formates, the stimulating properties of which are not attained at the expense of the blood pressure. Their action is muscular, while their effect is much more lasting. Clement and Huchard have already shown that formic acid is a powerful stimulant of striped muscle, and also improves the appetite and general nutrition. In concentrated form the drug produces a rise in blood pressure, but in the form of a 25 per cent. solution the increase is so slight as to be of comparatively no importance, even in advanced arteriosclerosis. The formates also possess a diuretic action, and in sclerosis of the kidney have been found to exert a marked influence in diminishing albuminuria.

From this experimental evidence it would appear that formic acid and its salts might be of considerable value in diphtheria, and the statistics of one hundred cases presented by Croom seem to bear out this fact. All the patients received the 25 per cent. formic acid solution in 5 to 20 minim doses for ten to fourteen days after admission to the hospital (the Edinburgh Fever Hospital). Otherwise the treatment was the usual one for diphtheria, including the use of antitoxin. This series of cases was compared with an equal number which were treated in previous years without the formic acid. The death rate from cardiac failure was apparently reduced from 8.6 per cent. to 2 per cent., and some of these cases had shown evidences of such cardiac involvement as to warrant a very bad prognosis. In the two patients who died the toxemia was profound before the first administration of the drug. The main features in all the cases were the marked regularity of the pulse, even after a previous irregularity had been present, and a noticeable improvement in the general nutrition, which points to a successful combating of the toxemia. The number of instances in which paralysis occurred was very small, only 3 per cent., so that, considered with the other favorable factors, we seem to be quite safe in concluding that in formic acid we have a remedy which is worthy of more extended trial.

NEPHRITIS OF PRENATAL ORIGIN IN THE YOUNG.

NOTWITHSTANDING all that has been done to discover the etiology of the nephritis of pregnancy, we are still far removed from a solution of the problem. And this uncertainty also extends to our knowledge of the changes which take place *in utero* in the kidneys of the fetus in cases in which the mother is suffering from any one of the many manifestations of renal diseases. That some definite relation exists between these conditions is shown by scattered reports of observers who have found a tendency to nephritis in several generations. The appellation "heredity" will hardly serve to account for these phenomena, and "hereditary tendency" is also insufficient. It seems reasonable to assume that in certain cases these lesions may be instituted during fetal life, or, as expressed in a recent article by Gillmore in *Surgery, Gynecology, and Obstetrics*, November, 1906, "the lesions in the fetal kidney occur because the toxins in the nephritic mother have damaged the kidneys of her fetus" before the latter has been born.

In support of his claim, Gillmore refers to the pathological examinations in fetuses from eclamptic mothers in which distinct evidences of renal lesions were found. In some the kidneys showed a necrosis of the cellular elements, in others well-marked acute nephritis was present, and in none was there any doubt of this fact. There may be some ground for doubting that a fetus whose kidneys are comparatively passive during uterine life, dying before or soon after birth of an eclamptic or uremic mother, succumbed to the direct results of its own nephritis. This has no bearing, however, on the assumption

that it is possible for an antenatal impairment of the kidney to occur. Gillmore claims that the latter is an important factor in producing an early postnatal form of nephritis.

The fact has frequently been referred to in recent years that there are many more instances of insidious affections of the kidneys in the very young than was formerly believed. In many of these it is of course impossible to know in what condition the mother's kidneys were before the birth of the child, and it therefore can only be surmised how far she may be responsible for the damaged kidney in her offspring. But in view of the knowledge of such a possibility, the careful, conscientious, routine examination of the urine of every pregnant woman becomes more than ever a solemn duty, for not only are we dealing with important disturbances in the mother, but also with a probable renal involvement in the fetus.

This brings us to the question of therapeutics, and it is here that Ballantyne's views on prenatal treatment will find an appropriate application, for, admitting the possibility of fetal nephritis in every instance of maternal renal disease, the former may be influenced by treatment directed to the mother. If this does not prevent, it may at least modify nephritic lesions in the fetus. The subject is one of extreme interest, and further investigations should be instituted for the purpose of a better understanding of this important matter.

"RACE SUICIDE."

Our strenuous and versatile President deserves well of his country in that he has provided topics without end for discussion in the newspapers, clubs, and debating societies. The Panama Canal, the negro problem, universal peace and general war, trusts, railroad rebates, pure food, political expediency, labor combinations, race suicide, the civil service, spelling reform are only a few of the innumerable questions he has sprung from time to time upon the attention of the expectant nation—and he has still two years of activity. Such is the diversity of these subjects that no class of the community is without something to discuss. Among the topics of special interest to medical men, as well as to reformers in general, is that of "race suicide," by which is meant the restriction of child bearing. When this was first broached the country accepted the pronouncement with acclaim, and anathema was the man who dared affirm that a large family was anything but a blessing. The quiver was there and it must be filled, and blessed was the man who filled it. The fact was not recognized, however, that this question, like that of spelling reform, was one of sentiment *versus* natural law, and that no presidential bull could settle it.

There are two factors at work in the reduction of the birth rate—one artificial, the other natural. It is, of course, a deplorable fact that the number of children in some families is kept down by artificial means of prevention, but this cuts a small figure in the general falling off in the birth rate; the real factor and the one that counts is a normal sterility due to the working of Nature's law. This has been well put by Major Charles E. Woodruff in an article contributed to a recent issue of the *New York Times*. The writer recalls the well-known fact that in all living things, whether plants or animals, the number of progeny is directly proportional, in the long run, to the risks to which the young organism is exposed during the period preceding maturity, and also to the normal length of the reproductive life of the particular species. In order to maintain an equilibrium there must be an effective birth, that is a birth of an individual which will reach maturity, for every death—no more, no less. If conditions change so that more of the offspring of any two individuals reach maturity than Nature intended or expected, there will be overcrowding and the result will be a weakening of the species and a reduction in its reproductive power. Man can thwart Nature, in the case of the domestic animals, by protecting the young and supplying them with an abundance of nutriment, but he fulfills the natural law nevertheless by killing the superfluous young for food or restricting the increase by eating the eggs. The same is true in respect of the vegetable species cultivated by man.

In general, this natural law rules the human just as certainly as it does the lower animals or plants. In former times, and at the present day among uncivilized races, large families were the rule because all but the most robust of the progeny died of disease before reaching maturity and many adults died of violence as well as of epidemic disease. If the race were to survive, under those adverse conditions, the number of children must be large. With the advance of civilization came better housing, better feeding, and protection from violence and disease, and so the population tended to increase. But the increased luxury of modern times and the development of the intellectual side of man have conduced to bring about a proportionate weakening of the physical side and a lowered productiveness, aided in a comparatively slight degree, no doubt, by a voluntary restriction of child bearing.

The working of this law is still to be seen in the civilized world in the difference in the number of children born to the wealthy and to the poor. The birth rate varies, as a general rule, to which there are the usual exceptions, in direct proportion to social conditions. The very poor and the ignorant, those who live in misery and abject want, breed like rabbits and the poor children die like flies, but the birth rate among the wealthy and those of highest intellectual development is small. This is not always, indeed not usually, intentional, and there is many a couple living in luxury and with no material want unmet who would gladly give half they possess to have children to perpetuate their name. The artificial restriction of the family, so far as it is practised, is an evil and moreover entirely unnecessary so far as the race is concerned, for Nature will see to it that the world is not overpopulated. So far as the prevention of conception, and especially of the destruction of the fruit of conception, is concerned, the President is to be commended for declaiming against the evil, but such practices are less operative than he seems to believe. The declining birth rate in the higher classes of the community is Nature's work, not man's, and cannot be prevented by legislation or the writing of essays.

Postural Albuminuria.

Orthotic or orthstatic albuminuria is still one of the puzzles of physiological pathology. Many clinicians, such as Senator, do not attempt to differentiate the condition from other forms of so-called cyclical albuminuria which are evoked by physical exercise, diet, cold bathing, etc., whereas others endeavor to make of it a distinct clinical entity. Most authorities, however, agree in considering that if not directly due to a demonstrable renal lesion it at least indicates a functional incapacity of the renal filter, which sooner or later is likely to be followed by an actual nephritis. How largely theoretical what has so far been written on this subject really is is shown by the fact that Heubner (*Berliner klinische Wochenschrift*, January 7, 1907) states that until now no autopsy on a patient suffering from orthotic albuminuria has been reported. Unusual interest, therefore, attaches to the description which he gives of the clinical course and postmortem examination of a case of this affection occurring in a girl of ten years, who eighteen months after she first came under observation died as the result of a cerebellar tumor. The urinary condition was typical of postural albuminuria, the urine remaining perfectly normal as long as the child remained recumbent, but showing considerable amounts of albumin when she was up and about; casts were never present. At the autopsy the kidneys were found to be microscopically normal, and the microscopic sections, although they were searched through most carefully, revealed no changes, except such as Heubner considers are referable to the nature and duration of the terminal illness. These consisted in a well marked hyperemia of the small veins and of the capillaries, and in a slight degree of fatty degeneration of the parenchyma. In addition in one kidney a minute spot of atrophic kidney tissue was found, but the author expresses the conviction that these abnormalities had nothing to do with the tendency to albuminuria and that accordingly this condition may exist without there being any gross or microscopic renal lesion. An interesting point in connection with the case is the fact that the autopsy revealed evidence of an old pulmonary tuberculous lesion, although this had not been diagnosticated during life. French authors have pointed out that postural albuminuria not infrequently is a pretuberculous manifestation.

Influence of Thyroid Extract on the Development of the Embryo.

Clinical and experimental evidence is steadily accumulating to show what far-reaching an effect on metabolism must be ascribed to the thyroid gland. A novel suggestion emanates from Bleibtreu who, in the *Deutsche medizinische Wochenschrift*, January 3, 1907, describes the results obtained on administering thyroid extract to pregnant rabbits. Although the author's experiments are not yet terminated, sufficient work has been done to enable him to come to the conclusion that the effect of the extract is profoundly to modify the development of the embryo and apparently in some cases not only to prevent its development, but even to cause absorption of the newly formed tissues to take place. Bleibtreu presents his views somewhat as follows: Substances of mucoid or myxomatous nature normally are constantly being formed in the tissues, but are broken down again at about the same rate. This decomposition takes place in consequence of the action of a substance formed in the thyroid gland as is shown in the absorption of myxomatous material which takes place when thyroid extract is administered in myxedema. Such myxomatous substances are necessary, however, for the building up of the embryo, and therefore it is desirable that the action of these catabolic thyroid bodies should be inhibited at this period. Accordingly, during pregnancy there is a partial retention of thyroid products as is suggested by the swelling of the gland sometimes observed. In the same connection the author points to a somewhat similarly destructive effect on embryonic growth, which is manifested when the pregnant animal is subjected to the action of the Roentgen rays or to cholin injections, and he suggests that possibly these agencies may have the effect of stimulating this particular function of the thyroid gland. The possibilities suggested by this hypothesis are certainly very striking, even though they are as yet supported by but little actual evidence, but the profound influence on metabolism that thyroid extract is capable of exerting, in obesity for example, seems to justify an attitude of reserve in considering a theory that appears even as fanciful as this.

Distention of the Bladder with Oxygen.

Radiographers have discovered that by injecting oxygen into joints that are to be examined by means of the Roentgen rays, especially the knee joint, the distention produced enables more satisfactory pictures to be obtained than is the case under ordinary conditions. A somewhat similar suggestion is now made to facilitate the examination of the bladder by means of the cystoscope. Sometimes, notably when the bladder is very intolerant of distention, or when the urine is very turbid or there is a tendency to hemorrhage, it is difficult to secure a satisfactory view through the instrument when the bladder is distended with fluid. Nitze attempted to cope with this difficulty by injecting air instead of the customary boric acid solution, but abandoned the practice because of the possibility of producing air embolism or of causing infection by germs carried into the viscus with the admitted air. Burkhardt and Polano (*Münchener medizinische Wochenschrift*, January 1, 1907) hit upon the idea of employing oxygen for this purpose, because its use would be free from the two objections just mentioned, and on trial they found that another supposititious drawback, that of lessened clearness of the cystoscopic picture in the absence of fluid, did not exist. The oxygen was generated from peroxide of hydrogen by the use of potassium permanganate and was therefore sterile. Its introduction into the bladder was found to be much less uncomfortable to the patient than the use of fluid, especially in cases of vesical irritability. If the gas is admitted slowly and only to the point of moderate distention as evidenced by the patient's feelings, no danger to the bladder need be apprehended, and the heat of the electric bulb of the cystoscope is also not found objectionable. Roentgen ray photographs of the bladder distended with oxygen were found much more satisfactory than those made when the organ was distended with fluid, and the authors regard the method as a distinct advantage in making radiographs when the presence of calculi is suspected. They even go so far as to suggest that more satisfactory radiographs of renal calculi may be obtained by slightly distending the pelvis of the kidney with oxygen admitted through a ureteral catheter.

The Etiology of Epilepsy.

Among the many causes assigned for the production of epileptic seizures considerable interest attaches to the theory which ascribes the condition to the presence in the blood of a toxin. An Italian investigator, Ceni, injected the blood serum derived from epileptic subjects into other epileptics and found that the injections were without effect or produced symptoms of acute poisoning. Injections made with blood from healthy subjects had absolutely no effect on epileptic patients. Ceni concluded from this that the blood of epileptics contained some toxic material and claimed that by continued injections immunity against this particular poison could be obtained. In some of the patients the clinical symptoms became worse, but in the majority he claimed to have obtained a beneficial effect. Schuckmann, writing in the *Monatsschrift für Psychologie und Neurologie*, Vol. 19, No. 4, says that he has subjected the serum from epileptics to a similar series of tests and obtained results completely in opposition to Ceni's, for in no instance was any specific reaction obtained. In this instance Ceni's theory seems effectively contradicted, and it therefore fails to offer any solution of the problem of the etiology of epilepsy of which a satisfactory explanation is still desired.

Radiotherapy in Trachoma.

Among novel methods for treating this form of conjunctivitis attention may be called to a suggestion made by Dinger in the *Wiener klinische Wochenschrift*, No. 42, 1906, who employs radium bromide for this purpose. Five milligrams of the salt was enclosed in a glass capsule two millimeters in diameter, and this was fastened to a small hard rubber rod. At first the radium was applied for one minute at a time twice a week, and later the time of application was extended to ten minutes. A well-marked reduction in the granules could be noticed after a few sessions, and no injury to the eye occurred. Among sixteen cases treated by this means a complete disappearance of the evidences of the disease resulted in seven. The younger the patient the quicker the effect was obtained. When a complicating pannus was present a longer term of treatment was required, but here also a cure resulted. Among the advantages which favorably distinguish this method of treatment from others which are at present employed are the ease and painlessness of application and the fact that it can be carried out without confining the patient.

The Frequency of Tuberculosis.

Statements as to the relative frequency of tuberculous disease in the human subject vary within wide limits. This is particularly evident in an examination of autopsy statistics. Heller and Orth, for example, find tuberculosis present to the extent of from 27 to 35 per cent. in 8,770 cases examined by them, while Naegeli and Burkhart, in a series of 1,546 cases, place it at 91 to 98 per cent. Although there is little doubt about the frequent occurrence of this disease, figures so enormous as these last can hardly be accepted without restriction. In a recent article on this question in the *Zeitschrift für Hygiene und Infectiöse Krankheiten*, Vol. 50, Kraemer states, and with truth, that it is hardly fair to base our conception of the frequency of tuberculosis on autopsy statistics of this character. Both Naegeli's and Burkhart's figures were obtained from the larger public institutions and industrial centers in a class of the population in which tuberculosis is particularly prevalent, and the results cannot therefore be applied to the race as a whole.

The Mentally Unstable in Illinois.

According to the biennial report of the State Board of Charities of Illinois, there are 58,000 mentally unstable persons in Illinois who are likely, under the stress of life, to become insane and be added to the wards of the State. The chapter of the report dealing with the new State psychopathic institute at Kankakee gives the first authoritative estimate of the number of "unstables." A careful attempt has been made to approximate the number of people in Illinois who are rated as mentally and nervously normal, but who are predisposed to insanity. Then follow the figures of the board, basing the estimate on those who are unstable because of hereditary weakness, or those with habits, such as the unwise use of alcohol, morphine, cocaine, etc., and those who suffer from certain infections. "This figure (58,000)," the report continues, "is a minimum. Twelve thousand of them are now in institutions. Probably there are more than 58,000 such persons in Illinois who today are productive members of society in some way. It is little short of calamitous that American medical education has not equipped the general practitioners to recognize the early symptoms of insanity in these unstable persons and give proper treatment in the early hopeful stages preceding and immediately following the onset of nervous and mental breakdown."

News of the Week.

Officers of the Medical Society of the State of New York.—At the annual meeting of this society, held in Albany this week, a report of which is presented in another column, the following officers were elected: *President*, Dr. Frederick C. Curtis of Albany; *Vice-Presidents*, Dr. Julius C. Bierwirth of Brooklyn; Edward Torrey of Olean, and Nelson G. Richmond of Fredonia; *Secretary*, Dr. Wisner R. Townsend of New York, reelected; *Treasurer*, Dr. Alexander Lambert of New York, reelected.

Public Lectures on Problems of Insanity.—The second lecture of this series, arranged for by the Psychiatrical Society, will be delivered by Dr. August Hoch (of Bloomingdale Hospital) at the Academy of Medicine, on Saturday evening, February 2, 1907, at 8.30 P.M. The subject will be "The Manageable Causes of Insanity," concerning which Dr. Hoch will present the modern facts and views. The aim of these lectures is to arouse in the public a sound interest in questions of mental hygiene, and all interested in sociological work are invited.

The Section on Public Health of the New York Academy of Medicine, after having been discontinued for eleven years, has been reorganized. The first meeting was held on January 8, when various problems relating to the health of New York City in the past and present were discussed by Drs. J. G. Bryant, and H. M. Biggs and Mr. Geo. A. Soper. The next meeting will be held on February 12, the subject being "Disinfection." Papers will be read by Dr. R. T. Wilson, in charge of disinfec-

tion, Department of Health, New York City; Dr. A. C. Abbott, Chief of Bureau of Health, Philadelphia, Pa., and Dr. L. E. La Fetra, New York City. All physicians and others interested in the subject are cordially invited to attend. Dr. John S. Billings, Jr., is Chairman of the Section.

Report of the State Lunacy Commission.—The annual report of the State Lunacy Commission shows that at present there are in the State institutions 28,302 patients, and there was during the last year an increase of 5,701 in the number of insane in the State. The report states that 1,468 patients were discharged as recovered, while 1,142 had recovered sufficiently to resume a life of unrestraint. The State last year expended $5,722,429 in caring for the insane, which was at the rate of $353 per capita, including salaries of employees and medical attendance. The so-called after-care system inaugurated by the State Charities Aid Association has been found very successful, and a definite plan has been adopted by this organization for looking after patients discharged from State hospitals in order to tide them over the first period of stress to which they are subjected upon resuming life in the community. The needs of the metropolitan district are made the subject of a special recommendation, for the State's lease of Ward's Island expires within the next six years, and the commission requests an immediate appropriation to provide a site for entirely new establishments. The commission specially favors the extension of the plan of farm colonies in connection with the existing State hospitals and speaks highly of the results of treatment at such of the hospitals as have these rustic adjuncts. Excellent results in the treatment of tuberculosis in the new sun pavilions recently erected at Binghamton and Ogdensburg are reported. The commission also makes a special plea for appropriations to permit the construction of nurses' homes on the grounds of the three State hospitals. Each of these homes is designed for 150 nurses and is estimated to cost $75,000. The commission reports the finishing of the large nurses' home at the Kings Park State Hospital, which now accommodates 200 employees of this class.

A New Child Labor Bill.—An effort to meet some of the objections to the Beveridge child labor bill has been made in a measure, introduced by Senator Simmons of North Carolina. This bill makes it unlawful for an interstate carrier to transport from the State of production into another State products of a mine or factory in which child labor is employed or permitted to work in violation of the child labor laws of the State in which the factory or mine is situated. The bill differs from the Beveridge bill in that it does not undertake to make a Federal child labor law, but recognizes the child labor laws of the several States and seeks to make them effective. It is based upon the idea that nearly all the States have child labor laws and that they are largely ineffective and will remain so as long as they can only be enforced by local prosecution for their violation.

Medical Legislation in Hawaii.—Dispatches from Honolulu state that the local medical association is endeavoring to have the legislature enact a law requiring all examinations for licenses to practise medicine to be taken in English. This movement is said to be the result of the granting of a license to a Japanese physician. The law as proposed is not aimed specifically against the Japanese, but as these constitute the preponderance of foreign candidates, the intention is clear.

Appropriation for Medical Inspectors in Chicago.—This city has appropriated $15,000 for the appointment of one hundred additional inspectors to cope with the epidemics of scarlet fever and diphtheria. The health department publishes figures relating to the results of school inspection, as regards diphtheria and scarlet fever. There was at first a gradual falling off in the number of cases of scarlet fever and diphtheria following the appointment of additional inspectors, but an increase in the violence of the scarlet fever epidemic has since occurred, 407 new cases of the disease having been reported on January 29.

St. Lazare Prison of Paris to be Torn Down.—The famous prison of St. Lazare, which has been one of the historic landmarks of Paris, is to be pulled down and its site to be covered with open squares and fine modern buildings. St. Lazare, as its name indicates, was built as a leper's hospital in the eleventh century, but on the disappearance of the disease from France was converted into a religious institution and later into a prison for women.

Behring's Tuberculosis Cure.—Prof. Behring is taking the first steps toward making his method of antituberculosis immunization available for general use. He calls his remedial agent tulaselactin, and has instituted a course of lectures and practical demonstrations to illustrate its method of administration. The courses are being followed by medical officers of tuberculosis sanatoria throughout Germany, and for all who seek to employ the new treatment attendance is an essential condition because Prof. Behring intrusts the preparation only to those who have qualified under his own supervision. The cable states that Prof. Behring is on the verge of a nervous breakdown and will soon enter a sanatorium for treatment.

Red Cross Aid for China.—The Red Cross officials announce that $17,000 has been collected for the China famine fund, and that of this amount $5,000 has been cabled to the American consul at Shanghai. It is also planned to send 5,000 bushels of wheat to be used for the spring planting.

Smallpox on Shipboard.—Owing to the presence on board of a case of smallpox the steamer *Gallia*, which arrived last week from Mediterranean ports, was detained at Quarantine and fumigated, and all the passengers who had been exposed were vaccinated.

Surra in the Philippines.—The Department of Agriculture is making great efforts to prevent the introduction into this country of surra, which is common among the live stock in the Philippines. As it is considered possible for an insect to convey the infection even after an animal has been found healthy on being taken on board of the vessel in which it is to be shipped, the department has forbidden the sending to this country of any animals from the Philippines, and even the pet dogs of officers are considered as coming under the ban.

Nitric Acid from the Atmosphere.—It is announced in the London papers that Sir William Crooks, in conjunction with some of the scientists of the University of Freiburg, has succeeded in discovering a process by means of which nitric acid may be extracted from the atmosphere in such a way as to make it available for commercial, industrial, and agricultural purposes.

Quick Professorship of Biology.—Dr. George H. F. Nuttall has been appointed to the Quick Professorship of Biology, University of Cambridge,

England. The chief duty attaching to the chair is the advancement of the study of "protozoa," especially such as cause disease.

Dr. Alfred Wiener has been appointed attending surgeon in the aural and laryngological department of Sydenham Hospital.

Stony Wold Sanatorium.—At the annual meeting of the managers of this institution held last week, under the presidency of Mrs. James E. Newcomb, it was stated that of the 193 patients treated in 1905 at Stony Wold 113 were discharged and 80 remained at the close of the year. The receipts were $111,463 and expenditures $107,000. There is $26,000 as a nucleus for a permanent endowment fund. Many improvements have been made and a model dairy supplies milk at three cents a quart in summer and four cents in winter. Mr. John D. Rockefeller and Mr. Anson F. Flower have each made a conditional offer of $12,500 if the institution succeeds in paying off its indebtedness, amounting to about $30,000, before March 1.

Dedication of the Ossining Hospital.—The formal dedication of the New Ossining Hospital took place on January 22. The new building, which cost $100,000, was erected in memory of the late Helen Ward Potter by her husband, Frederick Potter, a son of the late Congressman Orlando B. Potter of New York, and his sisters, Misses Blanche and Martha Potter, and Mrs. Walter Gerr.

Jewish Hospital for Deformities and Joint Diseases.—This institution has just been opened in this city. In connection with the regular hospital work there will be a course of lectures to teachers, instructing them in the causes of this class of diseases. They will also be instructed how to recognize the early symptoms of deforming diseases, so that the children may receive treatment during the earlier stages. The physician and surgeon in chief and chief of clinic is Dr. Henry W. Frauenthal of 783 Lexington avenue.

Maker of "Magic Boots" Acquitted.—After a trial lasting two weeks, in which large numbers of witnesses were called by both sides, the jury before whom the case of the so-called "magic boots doctor" was being tried handed in a verdict of not guilty. The defendant had claimed to be able to cure a long list of diseases by means of electrical and other curative properties alleged to be contained in boots which he sold at very high prices.

The Harlem Eye, Ear, and Throat Infirmary.—The secretary of this institution, Dr. C. B. Meding, states that there are several vacancies on the staff of assistants in the infirmary. Clinics are held daily from 2 to 3.30 and 6,000 patients are treated yearly. Those interested are requested to apply at the clinic, 144 East 127th street.

Indian Territory Twenty-third District Medical Society.—At the regular annual meeting of this society the following officers were elected for the coming year: *President*, Dr. Frank Bates; *Vice-President*, Dr. A. S. Spangler; *Secretary and Treasurer*, Dr. L. S. Willour. There were twenty-five members present.

Androscoggin County (Me.) Medical Association.—At the annual meeting of this association, held in Lewiston, it was voted that the minimum fee for life insurance examinations be fixed at $5. The officers were elected as follows: *President*, Dr. C. E. Norton; *Vice-Presidents*, Dr. H. H. Purinton and Dr. E. S. Cummings; *Secretary*, Dr. D. A. Barrell; *Treasurer*, Dr. B. F. Sturgis.

Dodge County (Neb.) Medical Society.—At the annual election of officers for this society, the following were chosen at the recent meeting held in Fremont: *President*, Dr. J. J. Metzinger, Fremont; *Vice-President*, Dr. Tandy Wigglesworth, Hooper; *Secretary*, Dr. A. P. Overgaard, Fremont; *Treasurer*, Dr. E. W. Martin, Fremont.

Union County (Ark.) Medical Society.—At the recent meeting of this society at El Dorado, the following officers were elected: *President*, Dr. Jno. Moore of Lisbon; *Vice-President*, Dr. S. E. Thompson; *Secretary*, Dr. J. B. Wharton; *Treasurer*, Dr. J. M. Sheppard.

Nashua (N. H.) Medical Association.—Officers were elected as follows at the annual meeting of this society held last week: *President*, Dr. Albert E. Brownrigg; *First Vice President*, Dr. Joseph A. Charest; *Second Vice-President*, Dr. James S. Black; *Secretary*, Dr. Eva M. Locke; *Treasurer*, Dr. Arthur L. Wallace.

Memorial to the Late Dr. Macdonald.—At a recent meeting of the New York Psychiatrical Society a memorial notice of the death of Dr. Alexander E. Macdonald, presented by Drs. Carlos F. MacDonald and William Mabon, a committee appointed for the purpose, was unanimously adopted and ordered to be spread upon the minutes of the society. The notice was in part as follows: "Alexander E. Macdonald, LL.B., M.D., a member of the New York Psychiatrical Society, died December 10, 1906. For thirty-five years Dr. Macdonald had been intimately associated with the insane. He commenced the study of medicine at Toronto University and was graduated M.D., Medical Department, New York University, 1870; LL.B., Law School, New York University, 1881. Lecturer upon Medical Jurisprudence in 1874; subsequently, Professor of Medical Jurisprudence, Professor of Psychological Medicine and Medical Jurisprudence, and was Emeritus Professor at the time of his death. House Physician, Hospital for Epileptics and Paralytics, Blackwell's Island, 1870; chief of staff, Charity and Allied Hospitals, Blackwell's Island, 1871. Resident Physician, New York City Asylum for the Insane, Ward's Island, 1874. Medical superintendent of the same from 1874 to 1904, the title of the asylum having been changed in the meantime to Manhattan State Hospital, East, Ward's Island. In 1901 he established the tent treatment of the tuberculous insane, removing them from all communication with any unaffected patients. Dr. Macdonald was one of the most distinguished alienists of this country and a man of striking force of character. His far-seeing powers, his unswerving integrity, and his great executive ability qualified him in an extraordinary degree for his responsibilities. At all prominent medical meetings his activities were conspicuous. His commanding presence and lofty sense of duty will always be remembered by those who had the privilege to be acquainted with him, and his pupils in all parts of the country will pay many tributes to his memory. The Psychiatrical Society desires to spread upon the minutes this tribute to the memory of their late associate."

(Signed) C. MACFIE CAMPBELL, M.B.,
Secretary.

Obituary Notes.—Dr. ARNOT SPENCE of this city died on January 26 at the age of forty-two years. He was graduated from the Bellevue Hospital Medical College in the class of 1884. He was a surgeon in the Ninth Regiment and was visiting physician to St. Joseph's Home for Consumptives.

Dr. Charles W. Townsend of New Brighton, S. I., died on January 27 as the result of injuries received at the hands of a supposed burglar who entered his house the night before. Dr. Townsend was a graduate of the College of Physicians and Surgeons in 1890, and also of the School of Mines of Columbia University. He was vice-president of the Richmond County Medical Association and was a prominent figure in medical affairs on Staten Island.

Dr. Henry A. Le Barbier of Larchmont, N. Y., died of erysipelas on January 21 after an illness of about six months. Dr. Le Barbier was a native of this city and was fifty years of age.

Dr. Joseph Manning Cleveland of Poughkeepsie, N. Y., died on January 21 of pneumonia. He was born in Charleston, S. C., eighty-two years ago and received his medical degree from the College of Physicians and Surgeons in 1850. He was superintendent of the Hudson River State Hospital from 1867 until 1893.

Dr. Robert W. Gray of Boston, Mass., died on January 19 at the age of seventy-one years. He was born in Paris, Me., and received his medical degree from Bowdoin Medical School. He served in the Civil War and had practised in Pittsfield, Mass., and Kennebunk, Me., and for the last twenty-five years had been a resident of Boston.

Dr. Benjamin Hubbard of Plymouth, Mass., died on January 12 at the age of eighty-nine years. He was born in Holden, Mass., and received his medical training under the tutelage of his brother, Dr. Levi Holden of Plymouth and in the Westminster Medical College. He began practice in South Weymouth in 1844, but later removed to Plymouth, where he has resided ever since. About fifteen years ago he retired from active practice.

Dr. T. E. Nott of Spartanburg, S. C., died on January 9 at the age of seventy-six years. He was graduated from the South Carolina Medical College of Charleston in 1852 and began practice in Union County. He served as surgeon in the Confederate service through the Civil War, and in 1873 he removed to Spartanburg, where he practised for over thirty years.

Dr. Adam Shirk of Oakland, Cal., died on January 13 at the age of sixty-six years. He was a native of Pennsylvania and had been assistant superintendent of the Harrisburg (Pa.) Hospital for the Insane and assistant superintendent of the State Hospital for the Insane at Austin, Tex., before coming to California twelve years ago. For the last five years he had been superintendent of the Alameda County Infirmary.

Dr. Carl P. Proegler of Fort Wayne, Ind., died on January 16 of apoplexy at the age of seventy years. He was a native of Germany and served as assistant surgeon in the Franco-Prussian war. In 1877 he came to this country and located in Fort Wayne. He was prominent in medical circles and served for a number of years as secretary of the Allen County Board of Health.

Dr. Franz Kuckein of San Francisco died of appendicitis on January 10 at the age of fifty-four years. He was born in Danzig, Germany, and received his degree from the University of Munich. In 1888 he came to this country, and, after practising for a time in Oakland, he removed to San Francisco in 1891. He was consulting physician to the German Hospital, and in 1901 organized the German-American League of California, of which he was the president for three years.

Dr. William F. Hovey of Bay City, Mich., died suddenly on January 18 at the age of eighty-two years. He was born in Warsaw, N. Y., and received his medical education from the Cleveland Medical College and the University of Michigan. In 1865 he was detailed to the military hospital at Louisville, and later settled in Fenton, Mich., but removed to Bay City in 1876.

Dr. E. L. Wemple of San Francisco died suddenly on January 15 at the age of fifty-nine years. Dr. Wemple was a native of Jamestown, N. Y., and had practised in San Francisco since 1889. He was attending physician to the Clara Barton Hospital, of which he was president at the time of his death.

SEVENTH HARVEY SOCIETY LECTURE.

The seventh Harvey Society lecture was given at the Academy of Medicine on Saturday, January 26, the speaker being Prof. E. B. Wilson of Columbia University. The subject of the lecture was "Recent Studies in Heredity;" but this, the speaker said, was really too broad a title as he intended to devote himself to certain phases only of this interesting subject.

In the study of heredity three principal methods had been followed. The first of these was the statistical, which consisted in recording observations on a large number of variations, etc., as they occur in nature. Perhaps the best work of this description was that embodied in Galton's "Law of Ancestral Inheritance." The second method was the experimental. This consisted especially in crossing different types and observing the effect of this on the progeny. While there was little doubt that the same rules held for the crossing of pure bred forms, it had been found to be far simpler to study the crossing of hybrids, for then the different characters could be easier observed. The best studies along these lines were embodied in the work of Mendel, the formulator of the well-known Mendelian law. It might be mentioned in passing that the Mendelian phenomena were probably not so general as at first thought; they were extremely valuable, however, in having given us a new view of the subject. The third method, and the one to which the speaker had devoted some attention, was the indirect one, in which attempts were made to follow out the physical aspect of the subject from the side of the germ cells.

Before going on to the subject of this lecture proper, Prof. Wilson said it would be well to review briefly some of the more prominent facts in Mendelian heredity. One of the most important advances was made with the recognition of "unit characters," the transmission of which was absolutely different from "blending." A great many characters were blended; the result of crossing a negro and a white person was a mulatto. In many characteristics, however, inheritance was by means of unit characters instead of blending. In these the hereditary properties behaved as though they were material bodies. Prof. Wilson here exhibited several mice to illustrate the point in question. In the first jar was an ordinary wild gray mouse; this had been bred to the white albino mouse shown in the second jar. The result of this mating was shown in the third jar, and was a hybrid, looking just like the gray parent. Not a trace of white was visible, and yet within this gray hybrid the white of the other parent was latent. On breeding two such gray hybrids there were a pure white mouse and three gray ones. This white offspring was spoken of as a white "extracted" mouse. The result of breeding a large number of the gray hybrids

of the third generation resulted in pure white mice and gray mice in the proportion of 1:3. If several characters were taken the result while more complex was still quite mathematical. This was typical "Mendelian Inheritance." By a close study of the subject it had been found possible to work out in advance what the result of certain breedings would be, just as a chemist could predict by a study of his formula what the result of a chemical reaction would be.

The principle underlying the Mendelian law was very simple. When two characters were put together in a hybrid, *e.g.* G and W, the formation of the germ cells in this hybrid, was such that the characters were again taken apart, half the germ cells being G and the other half W. This was true both for the eggs of the female and the sperm of the male. When these hybrids then were bred we had the following possible combinations:

GG, GW, WG, WW

And as G (gray) dominated over W (white) this meant that there were three gray offspring to one white.

Although this was the essence of the Mendelian law, recent developments had shown that the subject was not quite so simple; certain qualifications were necessary. It would lead too far afield, however, to go into these, and so the speaker would go on to the subject proper.

It was now everywhere admitted that the physical basis of heredity was contained in the nucleus of the combining cells. In the nuclei, then, must be contained the unit characters, which we had just seen behaved almost as if they were material bodies. Now it had been found that the nucleus of the egg or of the sperm contained bodies, the history of which actually ran very close to that of the unit characters. These bodies were the chromosomes. These appeared in the fertilized egg and whenever the cell divided partook of this division. They were, therefore, the lineal descendants of those present originally in the fertilized egg.

Until recently it had been thought that all chromosomes were alike; now this was known not to be the case. One of the most striking differences was one in size. Disturbances of the chromosomes were followed by disturbances in the progeny, *i.e.* monsters were produced. It was therefore believed at present that the chromosomes were of a complex organization and that they had within them the various factors of heredity. It was thought, for example, that the part played by one of the smaller chromosomes was different from that played by one of the larger ones. The chromosomes were always in a double series, though this series was not often complete. It had been found, for instance, in the germ cells of the squash bug that those of the female contained 22 chromosomes, while in the male there were only 21. The double series just alluded to was now regarded as being made up of chromosomes respectively from the male and from the female parent, *i.e.* half from the egg and half from the sperm. There was considerable evidence for this assumption, and quite recently Prof. Monkhaus, by crossing species whose chromosomes were of different size and therefore readily distinguishable, had succeeded in tracing the two kinds of chromosomes throughout a considerable period of development.

Prof. Wilson then showed, by means of diagrams, how these cytological studies offered an easy explanation of the Mendelian phenomena. At a period just before the germ cells were formed the chromosomes paired. This process was called synapsis. This was followed by a cleavage or "reduction," as it was called, in which the maternal and paternal chromosomes again separated. As a result half of the germ cells were maternal in origin and half were paternal. The same held true of the sperm cells. On pairing it could be shown that this gave results which agreed mathematically with the Mendelian law. The speaker then reviewed and pointed out which of the foregoing were proved facts and which probably were pure assumptions.

These cytological considerations also offered a satisfactory explanation of certain forms of inheritance which did not conform to the Mendelian law. Blends, for example, could be explained by assuming that in the process of synapsis the pairs of chromosomes fused so closely as actually to become one. The germ cells resulting would then have those characters blended whose chromosomes had so united.

In closing the speaker said that if these conclusions possessed any considerable amount of truth they would probably be of great interest to physiologists and pathologists. The physiologist would be compelled to recognize that in the nucleus he was dealing not with one set of protoplasm, but with many different ones. To the pathologist the subject might prove applicable to the subject of tumor formation, for, as already stated, disturbances in the chromosomes resulted in the development of monsters. At the present time, to be sure, the cytologist could not offer much help to the pathologist; he still had enough troubles of his own. Finally, the speaker said, he wished his hearers to know that in inheritance we were dealing not with vague questions, but with clear, concise mathematical problems.

Correspondence.

OUR LONDON LETTER.

From Our Special Correspondent.

HOSPITAL SUNDAY FUND—LIVERPOOL CHILDREN'S HOSPITAL—COUNTY COUNCIL'S HEALTH REPORT—THE DIET OF TO-DAY—SPINAL ANÆSTHESIA—OBITUARY.

LONDON, January 11, 1907.

The Lord Mayor presided yesterday at a meeting of the Council of the Hospital Sunday Fund, when the committees and honorary officers for the ensuing year were elected.

Yesterday the Duchess of Albany went to Liverpool and opened the new building of the Children's Hospital, provided by the citizens at a cost of £68,000. In the course of the proceedings Mr. Maxwell, president of the hospital, traced its progress from its inauguration in 1851, as the pioneer children's hospital, to the opening of the building now demolished in 1800, on to eight years ago, when it was decided to pull it down. Medical and sanitary experts were consulted, and the present site pronounced the best in the city for the purpose. The building comprises two pavilions with accommodation for 100 beds, an administrative block, an observation block, a nurses' home, and laundry. The corporation has granted £1,000 during the last five years.

The report of the Health Committee of the County Council has appeared, and contains the report of the Medical Officer for the county for the year 1905. The death rate for that year is the lowest on record. It has fallen from 21.0 to 15.1 per 1,000, or nearly 30 per cent. since the Public Health act for London of 1891. But a high infantile mortality remains. It is suggested that this may be in some degree due to a more complete registration of infants surviving their birth for only brief periods. There is, further, an increase in the number of deaths registered as premature, or with congenital defects, etc. Some support of this view is afforded by the fact that while social conditions, as measured by overcrowding, seem to govern infant mortality in several districts, this is not observable for the first few weeks of life—a fact perhaps due to the less complete registration of the newborn. The rate of mortality from phthisis in 1905 was only half that of the decennial period 1861-70. The mortality from cancer has been

practically the same for several years. The increase in the last twenty years of the nineteenth century is probably due to more precise diagnosis. The Medical Officer devotes considerable space to the subject of food inspection and the absence of regulations of meat markets and abattoirs, which it is hoped legislation will soon provide.

On Wednesday, Professor Halliburton lectured at the Institute of Hygiene on "The Diet of To-day." We have of late been strongly exhorted to return to a "simpler life," to weigh Carlyle's opinion on "low living and high thinking." The Professor seems to think it is time to put in a word on the other side, for he began by saying that it was certainly unwise to overeat. He was of opinion that it was safer to eat rather too much than too little. The least one could do with was not the best, for nature did not, as a rule, work to minimums. He would not accept Professor Chittenden's views to the full, for the minimum diet was not necessarily the optimum. The terms nitrogenous and nutritious were sometimes erroneously used as synonyms. The nonnitrogenous foods are as essential as the nitrogenous, though utilized in another way by the system. Milk is such a perfect food because it contains both classes of nutriment. But milk, when tampered with, as it often is in the preparation of infant foods, loses its perfection, some of its constituents being removed from it. The lecturer admitted that a large amount of the proteid food we take is not utilized for tissue repair, but is thrown out as waste material, at the expense of undue work for the digestive and excretory organs. No doubt the majority of well-to-do people sin on the side of excess, and a reduction in the consumption of meat and alcohol would be a feature of the diet of the future. The Professor then referred to the dietary of the poor in large cities and the low nitrogenous intake in vegetarian nations, and said he held that they show less resistance to privation and disease than meat-eating people. This conclusion will no doubt be questioned, but I leave the Professor to the vegetarians. He next pointed to the good effect of extra feeding in the open-air treatment of consumption and in the rest cure for various nerve diseases. He thought the limitation of proteid to subserve the repair of tissue waste would mean living dangerously near the margin, and he quoted Dr. Leathes as saying that in infants ten times the minimum quantity of nitrogen necessary to serve this purpose was provided by nature, even allowing for growth. The explanation of this apparent waste, he said, was that certain constituents of the proteid molecule are essential for building up the tissues, and the amount in the proteid molecule is very limited, so the body must put up with waste material. The large size of the liver appeared to him an express provision of nature for dealing rapidly with this waste material. The easy digestion of animal proteids rendered them superior to those of vegetable origin, and the so-called vegetarians recognized this by taking milk, eggs, cheese. This sort of vegetarianism would perhaps spread if bad cooking could be excluded, for badly-cooked vegetables were more indigestible than equally badly-cooked animal food.

The subject of spinal anesthesia was rather fully discussed last month at the Gynecological Society. Interesting papers were read detailing cases, and specimens of tumors removed under its influence exhibited. Dr. Macnaughton-Jones gave some account of what he had seen in the clinics of Heidelberg and Freiburg. As he observed, the method was introduced by Bier in 1899, who used cocaine—experimenting on himself and assistant (Hildebrandt). Results were not encouraging, but Tuffier, in France, followed up the plan, and in 1900 reported 250 operations, 142 being laparotomies. In 1901, Hahn reported 1,708 cases, with 8 fatalities; Morton of San Francisco, 673. In 1904 Bier made the next advance by adding adrenalin and substituting stovain (first employed by Sonnenberg) for cocaine. Deenitz was associated with Bier in this work. From this time a host of workers have been reporting their experiences. Franz has had no death or serious symptoms in 180 cases. It is obvious that there are dangers to be reckoned with in this method, e.g. arrest of respiration from involvement of the medulla and motor nerves, collapse, spinal paralysis, sepsis, all of which have been fatal. The advantages claimed for this method are: avoidance of general anesthesia in cardiac disease and arteriosclerosis, also of the local and post-operative effects of chloroform and ether, as well as of the action of the abdominal muscles in laparotomies, etc. On the other hand, the disadvantages are vomiting (rather frequent), movements of the bowels in operations on the perineum, etc., insufficient narcosis at times, perhaps from rapid dispersion of the drug, collapse, respiratory paralysis, injury to motor nerves, headache, sepsis.

Dr. Swanton's paper detailed a case of hysterectomy for fibromyoma under spinal analgesia in a patient of 44. There was no pain except when the vessels in the broad ligament were seized preliminary to ligature. Then the patient felt a twisting and dragging, which also came on whenever the parietal layer of the peritoneum was drawn forward. There was also some nausea and straining. Peristalsis, too, came on and interfered with suturing, so A. C. E. was given. The convalescence was complicated with nausea and paralytic ileus requiring enemata of turpentine.

Mr. Charles Ryall's case was also one of hysterectomy, the patient aged thirty. During the operation the patient did not complain of actual pain, but when the uterus was drawn up said she felt something being pulled. She was nervous, had some vomiting, causing the intestines to bulge into the wound, and so making the operator wait until this passed off. The operation occupied forty minutes, and convalescence was uninterrupted.

Neither of these surgeons seem to regard the method with enthusiasm, but both consider it as useful in cases in which general anesthesia is contraindicated for any reason. Turning now to the discussion evoked, there was a good deal of agreement with this view. Mr. Canny Ryall said his experience extended only to thirty of forty cases, but he would not use a general anesthetic for operations below the level of the diaphragm when spinal anesthesia was available. In such a formidable operation as Kraske's he had had complete success with this method and no shock, although the patient was under the influence of the drug altogether for about six hours. Many operations on the lower limbs, appendix cases, and radical cure of hernia had been equally successful. The absence of shock impressed him most forcibly. He had also watched the effect on mucous membranes, and had seen no ill effects. Patients rarely suffered from sickness after novocain, and only a few had headache.

Mr. Spanton confessed he had no experience, but he gathered that 5 deaths had occurred at one of the foreign clinics, and at Freiburg, in 380 cases, 2 deaths—a very high rate of mortality. In most cases, too, vomiting was reported, and this is one of the drawbacks of general anesthetics in abdominal cases. He had not the dread of general anesthesia that some entertained.

Dr. Herbert Scharlieb, as an anesthetist, said stovain, novocain, etc., had come to stay. They were of great value, though they were only analgesic—not anesthetic. It might impede the operator, on the one hand, and increase shock on the other, for the patient to be aware of every touch. The objection to chloroform was its lethality, but he held that to be due to improper dosage. The present death rate of chloroform was 1 in 4,000, and up to the present that of novocain and stovain had been higher. He would avoid praising the new analgesics too highly as quite safe, or condemning them as dangerous.

Mr. B. Jessett (President) mentioned a case in which he performed appendectomy under spinal analgesia conducted by Mr. C. Ryall, when the pulse was observed by Dr. Swanton. It went at one time to 150, and the question was whether that was caused by the drug or by the operation, or the nervousness of the patient, who certainly seemed calm enough and was chatting all the time.

Dr. Giles congratulated Mr. Canny Ryall as a pioneer and told him not to feel discouraged if his colleagues waited further experience, for an open mind was the true scientific attitude.

Dr. E. A. Fardon died on the 2d inst. He was identified throughout his professional life with the Middlesex Hospital, to the service of which he gave all his energies. He was born in 1846. Some early years he spent in business, and entered the hospital as a student rather late. He took the double qualification in 1878-9, and then was appointed successively house physician, house surgeon, and obstetric assistant (resident). The resident medical officioship then became vacant and was offered him, and he held it for some thirty years, with the greatest satisfaction to all concerned. Indeed, many reforms in the hospital school were due to his initiative. All supporters of the Middlesex attribute much of its progress to the unwearied work of the late resident medical officer.

Surgeon-General R. C. Lofthouse, M.D., who died on Monday, entered the Army in 1854, and retired after thirty years' service. He was in the Crimean War and the Indian mutiny, was mentioned in dispatches, and was awarded several medals and clasps.

A New Retroversion Operation.—Freund suggests the following modification of some of the older procedures. The round ligaments of either side are shortened by a suture approximating two points a short distance from the inguinal and uterine attachments respectively: the loops thus formed are placed in front of the uterus, and are then sutured both to this and to the anterior abdominal wall. The author claims for this operation all the benefits belonging to ventrosuspension, with none of its disadvantages.—*Zentralblatt für Gynäkologie.*

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

FILARIA PHILIPPINENSIS—ITS POSSIBLE RÔLE IN THE SPREAD OF MALARIA—PLAGUE-CONTAMINATED ANTICHOLERA SERUM —PERSONAL.

MANILA, December 14, 1906.

THE regular monthly meeting of the Manila Medical Society took place at 8:30 P.M., December 3, 1906, at the St. Paul's Hospital. Dr. Musgrave, a member of the staff of that institution, gave a talk upon the use of the *x*-ray and a practical demonstration of the machine that is in use at that hospital.

A paper was next read by Captain Percy M. Ashburn, Assistant Surgeon, U. S. Army, and First Lieutenant Charles F. Craig, U. S. Army, upon the *Filaria philippinensis*. This paper was supplemental to the one which was recently published in the *Journal of Science* for September. Four additional cases were reported, the findings of which went to confirm the statements made in the previous paper written by them. A very important point was brought out by the writers, which has not heretofore been mentioned in connection with the spread of the blood diseases, that is, the rôle which the filaria or other animal parasites may play in acting as intermediate host for malarial or other protozoa. It is thought that, for instance, the *Filaria philippinensis* might harbor the malarial parasite, the filaria might be ingested by the mosquito, and perhaps the mosquito might inoculate man with filaria that contained malarial organisms. The filaria in the blood stream of man might undergo change or disintegration, or even without disintegration the malarial parasite might be set free. If this were true, considerable additional light might be thrown upon the transmission of disease, and our present views of the period during which malaria may remain in the resting stage would perhaps be considerably changed. It may be readily understood that if the foregoing hypothesis proves to be correct it would perhaps serve to explain some of the obscure cases of malarial infection which now do not seem to be fully covered by the mosquito theory alone. The writers promised to investigate this phase of the question and make the result of their work known later on.

The additional cases of filaria which were reported were found among native troops who are stationed in Cavité province, near Manila, after being reported by the medical officer in charge. They were removed to the First Reserve Hospital, Manila, where thorough studies were made and the diagnosis confirmed. It will be remembered that Drs. Ashburn and Craig claim that their filaria differs from others heretofore described, in that a tight sheath is present, that the head forms a serrated retractile band, and that the viscus forms a separate tube or cylinder, whereas in other forms it is either negative or shows in the form of a granular mass, and, with the exception of the *Filaria perstans*, the motility is lashing and progressive, and that it has no periodicity, being found with equal facility at any time of the day or night.

The lamentable accident, which was reported previously, which occurred among the prisoners who were inoculated by Dr. R. P. Strong, of the Government Laboratory, has so far resulted in 13 deaths among the 24 cases inoculated. The Governor-General, in order that a complete investigation of the accident might be had, appointed a general committee, composed of Señor Rafael del Pan, Dr. Gregorio Singian, Dr. José Donelan, Señor Carlos Ledesma, and Dr. Ariston Bautista Lim. In addition to the foregoing committee, a technical committee was appointed, consisting of Captain and Assistant Surgeon Percy M. Ashburn, U. S. Army, Dr. Luis Guerrero, and Dr. Juan Miciano.

The instructions to the general committee were as follows: "This committee will investigate and report in detail on the following subjects: (1) Is any anticholera prophylactic manufactured and properly prepared by the Bureau of Science, or used by the Government, or any of its authorized officials, dangerous *per se* to human life? (2) Is the anticholera prophylactic manufactured by the Bureau of Science properly, carefully, and scientifically prepared, and was the anticholera prophylactic used to inoculate the prisoners referred to properly, carefully, and scientifically prepared? In case the prophylactic used to inoculate said prisoners was not properly, carefully, and scientifically prepared, what person or persons are responsible for such improper, careless, or unscientific preparation of the prophylactic used? (3) Did the anticholera prophylactic used to inoculate said prisoners deteriorate or become contaminated after preparation, and if it did deteriorate or suffer contamination could such deterioration or contamination have been avoided by the use of proper care, and who or what was responsible for such deterioration or contamination? (4) Was there any carelessness or negligence in making the inoculations in question, and, if so, who is responsible for such carelessness or negligence? (5) What was the direct and the indirect cause of the death of said prisoners?"

The instructions to the technical committee were as follows: "The technical committee shall investigate the method of the preparation of the cultures that were used in inoculating the prisoners in Bilibid, their nature, and the possibilities of contamination, and the result that would follow the use of a prophylactic prepared by the method used in these inoculations; also the literature relating to cholera vaccinations and the results obtained therefrom in the past. To make a scientific investigation as to the cause of death of the prisoners in question, which must include a complete biological and pathological study by experiment and literature, and for this purpose authority is hereby granted to investigate, by autopsy or otherwise, any deaths that may hereafter occur among the inoculated prisoners, and to make blood examinations of the blood of the vaccinated prisoners still living. The technical and scientific investigations of the technical committee shall not exclude the consideration of technical and scientific investigations made by others, or the consideration of such other expert evidence as may be presented. The general committee is respectfully requested to hold a meeting as soon as possible, and jointly with the technical committee to take such steps as may be necessary for the making of the investigation and report required by this order."

Dr. W. S. Washburn, Chief of the Philippine Civil Service, who recently returned to the Philippines after spending leave of absence in India and the United States, has again been compelled to request six months' leave of absence, for the purpose of proceeding to the United States on account of ill health.

Progress of Medical Science.

New York Medical Journal, January 19, 1907.

The Ocular Complications of Mumps.—J. H. Woodward completes the history of a case previously reported. The patient was a girl of eleven years with left optic neuroretinitis following infectious parotitis, which resulted in blindness of the affected eye. Proptosis caused by anterior staphyloma called for enucleation three and one-half years later. Enucleation and possibly evisceration of the orbit was advised because it was not possible to state positively that malignant degeneration had not begun within the eyeball. The probabilities, however, were strongly against that supposition, for there was no history of prolonged pain, the intraocular tension, although greater than normal, was not high, the proptosis was evidently not due to an increase in the contents of the orbit behind the eyeball, the development of the anterior staphyloma had been very slow (one year), and the general health of the patient was and had been, with the exception only of acute illnesses, excellent. There was some swelling of the right optic disk at the upper and lower borders. The vessels of the right fundus were tortuous, but the function of the eye was not affected; vision was normal. The report of the pathologist on the enucleated eye is given in full. Although carefully searched for, no evidence whatever of malignant disease was found. The case was one of proliferating neuroretinitis due to mumps. The proptosis was a consequence of the increased intraocular tension from secondary glaucoma produced by obliteration of Fontana's spaces and Schlemm's canal.

Gastroptosis a Causative Factor of Tachycardia.—H. Weinstein outlines the characteristics of paroxysmal tachycardia. The etiological factor is often difficult to find in a given case. It may be that it is of a reflex nature brought about through interference with the proper functioning of the vagi. The author gives the history of a woman of twenty-six years, married and extremely anemic, who had suffered from palpitation for eight months. A soft systolic murmur was heard at the apex. The abdomen presented on inspection a considerable depression in the epigastric region; the lower abdomen bulging forward and rounded; the abdominal walls soft and flabby. The greater curvature of the stomach was found to occupy a position about midway between the umbilicus and the symphysis pubis; the lesser curvature somewhat above the umbilicus. A splashing sound was easily elicited, the stomach containing considerable gas and fluid. There was no visible peristalsis of the stomach as is sometimes observed in severe gastroptosis. The liver was palpable somewhat below the costal margin, and the right kidney was freely movable. The deep reflexes were only slightly exaggerated. The pulse was small and rapid (120 per minute) and easily compressible. The urine presented no abnormalities. It was

conjectured that the prolapsed stomach stood in a causative relation to the tachycardia. The wearing of a proper abdominal bandage promptly relieved all untoward symptoms. It appears reasonable to assume that the prolapsed stomach, dragging upon the vagi, interfered with their proper functioning, thus causing tachycardia.

Education, Considered from a Medical Point of View.—R. Parsons condemns the modern forcing system of education of girls and claims that they are called on to do too much indoor studying and are not allowed to take the proper amount of exercise in the open air. The higher educational methods do not develop girls into healthy or refined women. Large numbers of young girls who are blossoming into womanhood and who will in the course of time become the wives and mothers of the American people, suffer from more or less impairment of the general health. Instead of being strong and robust, they are threatened with a physical breakdown. The nervous system is developed at the expense of other bodily organs. Moreover, the girls become masculine and slangy. They may be learned in certain forms of book knowledge, but do not exhibit that modesty of demeanor which is one of the most admirable traits of the feminine character. They tend to become eccentric. Parents are largely to blame for this state of affairs. They warn their daughters who are in the grammar grades that active play is unbecoming to a young lady. This fact, together with long hours of study in school and at home, deprives the growing girl of the opportunity of taking a sufficient amount of physical exercise in the fresh air and sunshine, of which she is so much in need. As time goes on the already overtaxed girl is expected to take up the study of some accomplishments, such as painting or music, and as the result of the constant effort to keep up with her studies at school and at home, the young girl is obliged to sit up late at night poring over her books, and is thus deprived of the proper amount of sleep. Soon the appetite is impaired, and she becomes listless and fretful, while it is not uncommon for her to develop symptoms of anemia. Moreover, parents must bring pressure to bear upon the educational authorities so that the conventions may be properly modified.

The Chemical Value of the Differential Blood Count in Operative Otology.—J. F. McKernon believes that in septic cases and particularly when distinct symptoms and physical signs are absent, the differential blood count is of practical value in enabling us to complete a diagnosis, and in cases of sepsis, when the physical signs and symptoms are distinct and definite, it is then only confirmatory of what is already present, and gives us an added link to complete the chain of evidence. In doubtful cases, when a differential count is taken and found to be negative, other daily counts should be taken in order to verify or disprove that which has formerly been taken. Another fact of importance brought out in this series of cases is that when cellular bone structures, like the mastoid bone, are involved in a septic inflammation, without involvement of the adjacent blood currents, we find that in the majority of cases the differential count shows a relatively lower polynuclear percentage than when a septic process is present in the soft tissues of the body. This can be explained on the theory that an absorption of toxins is less rapid when such a process takes place in a bone cavity than when the soft tissues of the body are involved, for in a number of the cases operated on, an abundance of pus was found, when the count showed a polynuclear percentage of between 72 and 80.

Journal of the American Medical Association, January 26, 1907.

Osteoatrophic Changes in Chronic Joint Disease.—R. S. Lavenson reports a case of chronic joint disease involving practically all the joints of the body. The most striking feature of the case was the wasting of the bones, which was especially marked in the hands. All the fingers were greatly shortened and some entire phalanges had apparently been absorbed. Before the appearance of her disease the patient, a woman, had been about 5 feet 3 inches in height, weighing in the neighborhood of 135 pounds. In her present condition her height, as nearly as it can be estimated in her crooked state, is not over 4 feet 10 inches. Lavenson has found but one case in the literature that seems closely to resemble this, that reported by Watson (*British Medical Journal*, March 10, 1906). Lavenson remarks that the extraordinary degree of atrophy in this case suggests some influence other than that of the local joint disease as playing a part in bringing about the conditions. The most rational consideration is naturally of some trophic disturbance, either primary or reflexly induced by the joint disease.

Frontal Sinus Variations.—M. H. Cryer illustrates and describes a number of variations in the frontal sinuses, including cases of multiple, unilateral, irregular, exaggerated, and absent frontal sinuses. He remarks that the frontal sinus is subject to infinite variations; it may be wanting, it may be very small, it may be single or multiple, and it may vary greatly in extent in different individuals and on different sides in the same individual. He has found two cases in which the internal plate or wall of the sinus was lacking, or incomplete, and also cases in which the so-called ethmoid cells have pushed upward into the space of the frontal sinuses. He considers all these variations are not the rare exceptions as some may claim, but thinks that any thousand skulls, if carefully examined, would show equal variations with those he describes, and if a series of a thousand skulls with diseased pneumatic sinuses were examined, the variations would be found much greater and more common. External evidence of these anomalies is generally wanting, and examination through the nasal fossæ will give but a slight idea. Transillumination does not give sufficiently accurate information, and clinical experience counts for little. A good radiogram, particularly if stereoscopic, is one of the most reliable witnesses for the surgeon's dependence in diagnosing the character of abnormalities and disease in the frontal region.

The Right and Left Frontal Lobes.—W. C. Krauss gives an abstract of the previously reported history of a patient with glioma of the right frontal lobe of the brain, in which the symptoms were merely severe pain and optic neuritis, most pronounced on the right. He also reports in full detail the history of another case of glioma of the left frontal lobe, in which, together with the symptoms of headache and optic neuritis, there was marked mental apathy resembling a mild type of acute dementia, with the consequent symptoms of slowness and hesitancy of speech, loss of memory and ideation, but no paralysis or localized spasm. There was vertigo and, possibly allied to this, atactic gait, as pointed out by Bruns as existing in frontal lobe tumors, was very noticeable. A very important symptom was agraphia both for printing and writing, but more marked for printing, before operation. After the removal of the growth the agraphia partly subsided, although a large part of the second frontal convolution, accepted by Gordinier as the localizing center for writing, was removed. The cause of this is only conjectural. Krauss discusses at some length the question of the function of the frontal lobes, and summarizes his conclusions as follows: 1. The prefrontal lobe of the left hemisphere is in all probability the seat of memory, reason, intuition and judgment, or the higher intellectual faculties. 2. A distinct center for writing and printing exists in the base of the second frontal convolution of the left hemisphere.

The Opsonic Content of the Blood of Infants.—S. Amberg has tested the opsonic content of the blood in infants, breast-fed and otherwise, and in different conditions of health and nutrition. The bacillary species used was *Staphylococcus citreus*, and the results in the different groups are given in tabulated form. His results do not altogether support Moro's finding that the blood of breast-fed infants always exceeds in bactericidal power that of other infants; while the kind of food may exert an influence, other factors must enter into consideration. One of these appears to be the state of nutrition, but there are indications that there are still other factors that come in play in certain cases. While he admits the insufficiency of the data, the small number of cases (45), and the fact that dispensary material is not altogether ideal, he offers tentatively the following conclusions: 1. The opsonic content of the infant's blood does not seem to follow the rules laid down by Moro for the bactericidal power of the blood. 2. The average values for the opsonic content of infants' blood exceed those laid down by Simon for normal adults. 3. A distinct advantage seems to exist in favor of the breast-fed infant. This advantage does not seem to be dependent so much on the breast feeding as such, as to some extent on the state of the nutrition of the infant and perhaps on the constitution.

The Roentgen Rays and Malignant Disease.—E. G. Williams suggests the possibility of a close relation between the vibration period of *x*-rays and that of atomic or subatomic activities that constitute the vital principle in protoplasm. It is the cells, and these in proportion as they exhibit the manifestations of life, that are principally acted on by the rays, and this explains the selective action on malignant growths, especially carcinomas, that have the largest proportion of vitally active cells. In the treatment of tumors, therefore, the result depends on their constituent cell tissues and their accessibility to the proper quality of radiant energy. Hence the adaptability of the rays for superficial malignant growths, while for deeper ones excision is indicated, followed, of course, by sufficient exposures to the rays to destroy malignant cells that may be left. Ex-

cision should also be practised in the case of cancer of the lips or of any mucous membrane, as he has found such for some reason especially resistant to the rays.

Antigonococcus Serum in Epididymitis.—G. K. Swinburne has employed the antigonococcus serum of Rogers and Torrey in thirteen cases of epididymitis. He was able to trace eleven of the patients through the whole course of their ailment. Eight were treated within twenty-four hours of the beginning of their symptoms; three had had the trouble three or four days. Three patients received two injections, four received three, two received four, and two received five injections. In three patients who received two injections twenty-four or forty-eight hours apart, there was apparent complete recovery in a few days, then a slight relapse requiring another injection (which, if used before, might have prevented the relapse). The injections were given as Dr. Rogers gave his, on the back of the arm, with due aseptic precautions. In all the cases but two the patients had no pain after the fourth day, except in the three who relapsed. In five there was left no trace of the disease, in four there was a slight nodule, and in two there was a rather soft mass left about the epididymis. Four of the cases were severe from the start. Swinburne believes the serum had a distinct effect in all the cases, markedly modifying the course and shortening the duration of the disease, and in several of the cases the quickness of the recovery was remarkable.

The Lancet, January 12, 1907

Persistency of Infection in Scarlet Fever.—H. P. Berry gives some facts derived from an epidemic in Grantham. In addition to the usual hospital isolation a nurse was employed to isolate and subsequently disinfect the cases remaining at home. The disease continued to spread and the author's attention was drawn to the possibility of infection being conveyed by means of those patients who had apparently recovered, and he has been forced to the conclusion that the infection may in certain cases remain in the patient very much longer than has been generally supposed. According to his investigations there were nineteen cases which, after apparently complete recovery and disinfection, gave rise to twenty-eight other cases, and he has reason to suspect that not a few others were due to this cause. It is also evident that this persistency of infection was not confined to patients treated in hospital, for three at least of these "infecting" cases were treated at home. Comparing these results with his previous experience, it appears necessary to presume that this persistence of infectivity may exist in some epidemics and not in others. Some twenty groups of cases are summarized illustrating the theory above advanced. The author notes the prolonged infectivity of a gleet after a gonorrhea is recognized as existing for an unknown length of time, and is inclined to the belief that the scarlet fever infection may similarly persist, lodged possibly in some of the nasal chambers, and that, moreover, it may lie dormant for some time until some suitable condition may render it capable of transmission. He is also inclined to the view that in some of those instances constantly referred to in text-books, when the poison is presumed to have been harbored in infected garments for a length of time, the spread of the infection may not improbably be due to the harboring of the infection in the convalescent patient rather than, as has been presumed, in the infected garments.

Treatment of Chronic Sciatica and Similar Forms of Neuritis.—A therapeutic suggestion is made by J. C. Webb, who reports four cases, and commends the use of static electricity. He calls attention to the fact that this form of electricity differs radically from currents derived from battery or dynamo on the one hand—whether continuous faradic, sinusoidal, or polyphase—and from "high-frequency" currents on the other. Its voltage is enormous, its amperage infinitesimal, and its frequency of pulsation (for it is not alternating in ordinary circumstances) anything that the operator wills. He employs for the class of cases under discussion the wave current, the brush and indirect sparks. With regard to early sciaticas and other forms of neuritis the author claims that invariably, if the patient be not too old, one can effect a rapid cure provided the case can be brought under treatment right from the onset. All forms of neuritis or neuralgia, provided they are not due to tumor pressure or other unremovable cause are among the most satisfactory of the many causes that can be cured or relieved by this most potent therapeutic agent.

Gallstones in the Appendix.—H. A. Ledraid reports the case of a man of twenty-six years who one month before entering hospital had had an attack of acute pain over the lower abdomen, from which he recovered. He resumed work and remained well for a while, but seven days before entering the hospital pain again returned about the umbilicus and gradually localized itself in the appendical region. There were no symptoms suggesting any trouble with the bile producing or conducting apparatus and no gallstones had ever been seen in the stools. His symptoms justified abdominal exploration, and the appendix was found to contain eleven gallstones, together with some turbid mucus. The patient made an uneventful recovery. The author states that as a general rule the size of stones met with in the gall bladder or separated from fecal discharge is too large to enter the canal of the appendix, and the same is true for the stones of fruit, formerly supposed to get into the appendix; the stercolith having simulated an orange pip or a damson stone. Here again a chemical analysis would effectually serve to get rid of a fiction which has been repeated in all books and is still believed in by some. The author suggests that all concretions found in or near the appendix, or in an abscess or otherwise, should be systematically examined by section and by analysis in order to settle definitely whether a concretion is a stercolith or gallstone, covered or not by fecal deposit.

Sclerodermia and Myositis.—Four cases are reported by J. A. Nixon, who briefly details others already in literature. He notes a polymorphism existing in the disease called sclerodermia similar, or rather analogous, to that of rheumatism. In the cases examined after death the muscle changes have been reported to be of either an inflammatory nature or of what may be interpreted to be a later stage of the nature of a fibrous degeneration or infiltration. The dependence of the disease and the allied muscular atrophies upon nerve lesions is but a matter of conjecture. No positive and definite nerve lesions have been described that could be regarded as standing in a causal relation to the malady. But the evidence of primary inflammation in the muscles of either an acute or chronic variety, ending as a rule in a fibrosis, is amply corroborated both by clinical and pathological facts. Beyond this it is difficult to penetrate clearly; the indications seem to point to an acute or chronic infection which affects mainly muscle and subcutaneous tissue, resulting in a sclerosis of the skin and the muscle, an infection to which perhaps persons suffering from other general diseases are peculiarly liable and especially the subjects of Graves' disease, myxedema, Raynaud's disease, Addison's disease, and nerve degenerations. It seems probable that myositis of a localized nature going on to sclerosis and contraction of a single muscle or isolated groups is commoner than generally supposed; and that the disease, of which this is only one manifestation, may run an acute, subacute, or chronic course, and on occasions may involve the skin, giving rise to one type of sclerodermia.

Pathology and Treatment of the Ocular Complications of Gonorrheal Infection.—W. J. McEttles believes that the Credé method of prophylaxis in ophthalmia neonatorum is too well established to call for more than mention. The incubation period of gonorrheal ophthalmia is sixty hours. We may have a true metastatic or endogenous infection due in some instances to the presence of the gonococcus or its toxin—this in addition to direct infection. He regards gonorrheal iritis as far more common than is generally supposed. In the usual conjunctivitis the progress depends on the condition of the cornea. If it is clear we may hope for good results. It is the author's practice at once to irrigate the sound eye and then instill a silver solution before putting on the Buller shield, since we have no ground for assuming its freedom from infection. The affected eye is then irrigated thrice daily with 200 cubic centimeters of a solution of nitrate, 1 in 300, in warm distilled water. After each irrigation, applied by a glass undine, he instills two drops of 2 per cent. nitrate and does not neutralize with salt solution. In all adult cases he divides the external canthus. This may seem a heroic proceeding, but in view of the extreme danger to sight it is insignificant. One blade of a pair of strong scissors is pushed under the commissure as far as it will go, and the intervening tissues are severed at a single stroke. The outer tarsal ligament is very resilient and will elude the grasp of any but sharp blades. It is remarkable how greatly this facilitates the proper handling of a case. The cornea is at once removed from pressure as the edematous lids are depleted by the free bleeding and orbicular spasm is also done away with. Even more valuable is the free access to the retrotarsal folds. Contrary to what one would expect, when all swelling has subsided, there is very little wound left and blepharoplasty is not needed, although that would be a simple matter if it were. During the interval between the irrigations it is usual to employ frequently renewed dressings kept moist and cold on a block of ice. As a general surgical measure, the use of cold topical applications is diminishing as a result of our increased acquaintance with the pathology of inflammation. This applies with unusual force to ophthalmic surgery, where there is *ab initio* a lessened vitality, in the face of which it is illogical to

reduce the normal temperature, and where, moreover, owing to the thinness of the intervening tissues, the temperature can be influenced to an unusual degree. Warm applications, on the other hand, maintain an impaired nutrition and are much more grateful to the patient than cold ones. When the stage of ocular gleet has been reached it will be found, as in urethral work, that simple astringents are of more use than the antiseptics.

British Medical Journal, January 12, 1907.

Peliosus Rheumatica.—M. W. Williams reports a case occurring in a boy of thirteen years with rheumatism in one knee. Two days afterward spots appeared on his leg. Still later on the right cheek, with a swelling of the eyelids and brow. Various other areas became involved. The joint trouble became polyarthritic, the boy had gastric and abdominal pain, and finally on the eighth day a free hemorrhage from the bowels, while he also spat blood. The gums were not spongy and did not bleed readily. On the following day the fever, which had run up to over 102° (mouth), disappeared. The urine showed no blood or albumin. The joint and abdominal pains disappeared and he was altogether better. During convalescence an urticarial rash appeared on the trunk and right leg, freely sprinkled with purpuric petechiæ. The entire illness lasted one month. The remedies given were salicylate of soda for the rheumatic symptoms and calcium lactate in ten-grain doses for the bowel bleeding.

Partial Dislocation of the Larynx.—H. Walker's patient was a male adult who while driving in a high dog-cart ran against a double clothes-line stretched across the road at the level of his neck. He was thrown over backward, had a feeling of suffocation, heard something "click" in his neck and became very dizzy and almost blind in his left eye. He was a veterinary surgeon with some knowledge of human anatomy and appreciated the nature of his accident, finding that the thyroid cartilage displaced toward the left. This displacement he was partially able to reduce. Examination four or five hours later showed an indentation but no fracture of the right ala. The hyoid bone was in position. The cricoid and upper part of the trachea were carried slightly to the left. No good view of the cords could be obtained with the mirror. The thyroid could be easily brought back into its normal position with a distinct grating sound. Voice was but little affected and there was no swelling, hemoptysis, edema, or emphysema. He was placed on his back with a straight splint to his nape. Strapping was firmly but gently applied and an ice bag laid against the left side of his neck. He recovered without special incident. The pomum Adami seemed to be permanently turned somewhat toward the left.

Anomalous Cases of Pernicious Anemia.—G. L. Gulland summarizes the histories of a group of cases in which prominent features were variously amaurosis, symptoms suggestive of peripheral neuritis, aphasia, gastrointestinal disturbances, kidney disease masking the anemia, acute Bright's, intermittent pyemia, long continued symptoms with acute terminal attack, etc. He believes that the disease is more common than fifteen or twenty years ago. He states that it is not essentially a blood disease at all, but rather a toxemia of largely unknown, possibly very various, origin, which affects the blood, the blood-forming organs, the nervous system, and the gastrointestinal tract, in proportions which vary infinitely in different cases. The old idea of pernicious anemia, that it is a condition of rapidly-advancing anemia leading within a short time to a fatal issue, must be given up, for cases are on record of very prolonged duration, and there are many in which almost from first to last the anemia is quite in the background, and the prominent symptoms are those due to the affection of one or other of the other systems mentioned. Treatment is of value only in cases in which a diagnosis is made early. The author does not believe that the streptococcus or any other organism is responsible for the malady. The blood of pernicious anemia represents in some ways a throw-back to the blood of early fetal life, and it seems possible that in the people who become affected there may be an inherent weakness of the resisting power and of the blood-forming organs which allows the bacterial processes which go on in every intestine to get out of hand, so that quite ordinary organisms acquire an unusual virulence, and set up the hemolytic and other toxic processes which one sees in pernicious anemias. The author has been strengthened in this feeling by the fact that within the last few months he has come across three cases of people in middle life whose fathers had died of pernicious anemia, in one case ten, in another twelve, and in the third eight years before. This seems to point to an inherited weakness of the bone marrow. He advances no new ideas as to treatment. Special stress is laid on diet. This is to be arranged with care to suit each case, but the broad principles are that as long as the blood count is low it should consist entirely of milk and farinaceous food; no meat of any kind should be permitted. Of course, this change of diet partly meets the second indication, the diminution of bacterial processes in the intestine. It is not uncommon to find that patients when they are first seen have large quantities of indican and similar substances in the urine, and that after a week or two on a farinaceous diet these practically disappear. In some cases it may be necessary to supplement this by giving intestinal disinfectants, of which in the author's experience calomel and salol are the most efficient, and in still others it may be necessary to wash out the bowel daily with large enemata of normal saline solution. Theoretically, the stomach might be washed out as well, but patients who are so seriously ill as to require this are seldom in a condition to stand the strain which it involves. The secretion of hydrochloric acid in the stomach is practically always deficient and usually absent in this disease, and he had sometimes found marked improvement from giving hydrochloric acid and pepsin in several doses after meals.

Berliner klinische Wochenschrift January 7, 1907.

When Should Laparotomy Patients Get Up?—Hartog says that during the last few years it has become the custom in Landau's gynecological clinic to allow laparotomy patients to leave their beds earlier and earlier. The present rule is to allow patients whose incisions were sutured without drainage, if no complications arise, to get up toward the middle or end of the first week, both after abdominal and vaginal celiotomies. The subjective feelings of the patients are largely used as a guide, and if the patient in reply to the question of whether she would like to get up replies in the affirmative there is no objection to her doing so even two days after the operation. An exception is made only in the case of plastic operations and hernia operations, but the getting up early is regarded as of especial importance and value when there are complicating constitutional diseases, such as diabetes. The author furnishes the details concerning a very considerable number of operations after which the patients were allowed to leave their beds very early, and states that no disturbances in the healing of the wounds were noticed and that all the patients left the hospital with firm scars and without any form of binder. Although the patients are apt to complain somewhat of discomfort in the wound on getting up early, they are all glad to put up with this in return for the satisfaction of leaving bed so soon. An especial advantage is the greater respiratory activity that is obtained, and this is of importance, particularly in dealing with old persons. Other points of advantage are the increased appetite and better digestive conditions as well as a lessened tendency to thrombosis and embolism.

French and Italian Journals.

The Serum Diagnosis of Tuberculosis.—According to the observations of G. Ferré and P. Courmont the positive value of the serum reaction, if it is furnished by the serum of apyretic individuals, constitutes in the great majority of cases a presumption of the existence of tuberculosis equivalent to certainty. On the other hand, in individuals suspected of tuberculosis the negative serum reaction is a sign of real value in relation to the absence of tuberculosis. Although this method cannot completely replace clinical diagnosis, it has a very useful application in the early diagnosis of tuberculosis. In addition to clinical diagnosis, it reveals the first stage in the evolution of tuberculosis. Seroreaction fails especially in very severe forms or in very advanced cases of tuberculosis. It is seen at its maximum in the cases which are on the road to recovery.—*Association Française pour l'Avancement des Sciences*, Lyon, August 2-7, 1906.

Multiple Primary Cancers.—F. Ravenna calls our attention to the commonly made statement that malignant tumors develop from a single primary lesion, from which the other lesions arise by diffusion. The author believes that there have been enough cases reported to determine definitely that there are a certain number of cancers in which there are two different primary foci resulting in two entirely different types of new growth. He cites numerous cases collected from literature, and to these he adds a case observed by himself, in which there was a stenosis of the esophagus of neoplastic origin and a tumor of the colon at the same time. The two tumors were of entirely different structure, one originating from the flat epithelium of the esophagus, the other from the glands of Lieberkuhn. The germs of cancer could hardly have been carried through the entire intestine, passing the digestive juices of the stomach and intestine without injury, and they could hardly have been carried by the lymphatic vessels through so roundabout a course as they must have followed to be carried from the esophagus to the colon.—*Il Policlinico*, November, 1906.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and First Annual Meeting, Held in Albany, January 28, 29, and 30, 1907.

JOSEPH D. BRYANT, M.D., PRESIDENT.

Monday, January 28—First Day.

HOUSE OF DELEGATES.

THE meeting of the House of Delegates took place at 8:30 P.M.

Report of the Secretary.—Dr. WISNER R. TOWNSEND, in this report, stated that there had been four meetings of the *ad interim* House of Delegates during the year 1906 and one meeting of the Council. There were now 57 county medical societies in the State, all of which had adopted new constitutions and by-laws in conformity with those of the State Society. Three counties—Essex, Hamilton, and Putnam—had no societies, and two counties—Queens and Nassau—had one combined society. The total membership in these societies on December 31, 1906, was 6,588. There had been no meetings of the District Branches, as it had been impossible to organize them in time, many of the county societies not having held their elections until December. In the future, the report stated, there would be nine meetings held in the State each year, eight by the District Branches and one by the State Society. The expenses of all these meetings would be paid by the State Society, after a satisfactory agreement between the Society and its Branches had been arrived at. During the past year effort had been made to secure the registration of two hundred and fifty legally qualified physicians in the State who had hitherto neglected this formality, and all but seventy were now registered in the County Clerks' offices. In view of the fact that a failure to register not only entailed certain legal penalties, but might render the individual liable to prosecution as an illegal practitioner, it was hoped all would see the importance of complying with the laws and promptly effecting registration.

Shortening of the Session.—Dr. LEO H. NEUMAN, chairman, reported that the Committee on Scientific Work had decided to have the scientific program completed in two days, instead of three, as heretofore.

Committee on Arrangements.—Dr. WILLIAM J. NELLIS made this report.

Report of the Treasurer.—Dr. ALEXANDER LAMBERT made this report, in which it was shown that the finances of the Society were in a satisfactory condition.

Report of the Committee on Public Health.—Drs. JOHN L. HEFFRON, chairman, HENRY C. HOPKINS, and HAMILTON D. WEY were the members of this committee. The report stated that during the past year there had been an awakening of the public mind upon some of the fundamental facts in public hygiene, such as no similar period of time had witnessed. The people had been aroused to the importance of pure food, and had enacted a law for self-protection which, if efficiently carried out, would effect an enormous diminution in the death rate. They had also come to a realization of the necessity of protecting the sources of the water supply from contamination with the excrement of animals or man, and from chemical pollution from factories. The committee commended the action of the American Society for the Advancement of Science looking to the formation of a National Department of Public Health, and suggested that the State Medical Society pledge its influence to carry into effect the plan which the committee of the American Society for the Advancement of Science should adopt. The committee recommended the establishment in every county of the State of a bacteriological laboratory, under the charge of a bacteriologist of recognized ability, to which every physician might send specimens for analysis. The appointment of health officers was at present in too great degree a political matter, and the committee recommended that the Regents should create the degree of Doctor of Public Health, and should grant it to such as have taken special post-graduate courses in the Science of Public Health in recognized schools of medicine, and that the State should enact a law making only such as have such a degree eligible to appointment as Medical Health officers. It was also recommended that the State medical license law should be amended so as to replace the three examining boards by a single board, before which all candidates should be examined in all branches, save only materia medica and therapeutics. By demanding the same education of all those who would practise the art of healing, the State would unify the profession of medicine, while, at the same time, it would deprive no man of his right to use any method of applying remedial measures that appealed to his reason, nor would it take from any individual the right of selecting the physician he might prefer.

Report of the Committee on Legislation.—Dr. ARTHUR G. ROOT, chairman, reported that thirty-six bills pertaining to the public health or the practice of medicine had been introduced in the Assembly last year, of which four were passed and approved by the Governor, and one was vetoed. In the Senate sixteen bills had been introduced, only one of which had become a law.

Report of the Committee on Publication.—Drs. E. ELIOT HARRIS, chairman, FLOYD M. CRANDALL, HERMANN M. BIGGS, ALEXANDER LAMBERT, and A. T. BRISTOW comprised this committee. The report was concerned chiefly with the rules which had been adopted regulating the admission of advertisements to the pages of the Directory and the State *Journal*.

Report of the Editor of the "Journal."—Dr. JAMES P WARBASSE presented a report on the ten numbers, March-December, 1906, appearing since he took charge. There was at first a deficit while the *Journal* was undergoing development, but it was now self-supporting. The paper could well be increased in size, the question being one of expense only. Every advertisement appearing in the *Journal* had first been favorably passed upon by the Committee on Publication.

Report of the Counsel.— JAMES TAYLOR LEWIS, Esq., presented brief synopses of forty-four malpractice suits which had been brought against members of the Society, fourteen lying over from 1905, and thirty instituted during the year. Many of these resulted in a victory for the physicians.

Officers.—The election of officers resulted in the following choice: *President*, Dr. Frederick C. Curtis of Albany; *First Vice-President*, Dr. J. C. Bierwirth of Brooklyn; *Second Vice-President*, Dr. Edward Torrey of Olean; *Third Vice-President*, Dr. N. G. Richmond of Fredonia; *Secretary*, Dr. Wisner R. Townsend of New York; *Treasurer*, Dr. Alexander Lambert, of New York.

Tuesday, January 29—Second Day.

SCIENTIFIC SESSION.

The first scientific session, held in the Common Council Chamber of the City Hall, was opened by a prayer by the Rev. Dr. J. A. Jones of the Madison Avenue Reformed Church.

President's Address.—Dr. JOSEPH D. BRYANT delivered this address.

Danger Signals from the Skin.—Dr. L. DUNCAN BULKLEY of New York read this paper, considering the importance of the skin as an emunctory organ of the body and as a regulator of heat. He considered briefly syphilis, eczema, acne, psoriasis, chronic urticaria, erythema multiforme and bullous eruptions, pruritus, xanthoma diabeticorum, boils and carbuncles, dermatitis maligna or Paget's disease of the breast, acanthosis nigricans with multiple capillary angiomata, lupus vulgaris, purpura rheumatica and erythema nodosum, petechial and erythematous rashes,

purpuric lesions, rose spots, pigmentary alterations, sweating, and dermatitis medicamentosa. He showed that the skin had vital relations with many parts of the body.

Dr. Frederick C. Curtis of Albany emphasized the fact that skin affections were largely connected with malaction, functional or otherwise, of internal organs.

Dr. L. Bolton Bangs of New York said that the danger signals in innocent infection from syphilis especially as regards deafness, could not be too strongly emphasized. It was in the early stages, if it could be discovered, that prevention of deafness might result from properly applied treatment.

The Importance of Aural Examinations and Functional Tests for Healthy People.—Dr. W. Sohier Bryant said that periodic examination of the ears should be made and functional tests applied at all ages, and after any general disease or affection of the upper air tract, inasmuch as serious damage to the ears might take place without the knowledge of the patient, due to inroads of insidious affections. When the individual was aware of the impairment, the pathological changes had advanced far enough to render recovery difficult. Whereas the early detection of the aural disturbance allowed adequate treatment, with the expectation of the prevention of aural vertigo, tinnitus, deafness, the danger of systemic affection, and intracranial lesions from middle ear suppuration.

Dr. Bisby Allen said a very large number of patients learned that one ear was almost gone before they became aware of it. Such could so easily be prevented if the parent would from time to time test the child's hearing with a watch. Deafness prevented by such a means would be a large asset to the State.

Dr. H. Lyman Davis of New York said that, in cases of hereditary tendency to deafness, the patient should be examined every two years.

Practical Legislation for the Prevention of Blindness from Ophthalmia Neonatorum.—Dr. E. Park Lewis of Buffalo said that the purpose of his paper was not to discuss the merits of different prophylactics in ophthalmia neonatorum. In a scientific medical society the following facts were accepted without discussion: That ophthalmia neonatorum was dependent upon an infection. That it was invariably absolutely preventable by either keeping the cocci from entering the eyes of the newborn child, or by destroying their virulence by the use of some germicide before they had had time to propagate themselves. Any one of several measures was effective, and the choice might safely be left to competent Boards of Health. While owing to better protective measures in the hands of hospital obstetricians and others, disastrous results were probably less frequent than formerly, the exciting cause of the ophthalmia was quite as common as ever, and in the hands of careless practitioners and midwives no protection whatever was afforded the child. Hence arose the necessity of protecting the helpless infant through legal measures. Of the means advised were (1) bills in the legislatures of the several States providing for the registration of births with the Boards of Health; (2) the distribution *gratuitously* by the Board of Health of lightproof, sealed ampoules containing the selected germicide to all physicians doing obstetric practice, as well as to midwives and to others making application for them, with advice as to the possibility of ophthalmia neonatorum developing, measures of protection, the necessity of immediate treatment, etc.; (3) requirement that on each birth certificate should be a signed statement that the germicide provided by the Board of Health, or some other accepted prophylactic, had been used in each eye of the child on the day of birth; (4) penalty in the event of the child losing the sight of one or both eyes, when the statement was not made that some measure of protection had been taken. Dr. Lewis asked for the indorsement of the Society as to the propriety of the enactment of the laws recommended.

Dr. Peter A. Callan of New York thought it was a sad commentary that it was still necessary to have a paper like the one just read before the Society, and the reason lay, he believed, in the indifference displayed by the general profession. It was all very well to have certain penalties on the statutes, but who was going to make it a business to carry out the provisions? He told of his efforts to have incorporated a contagious eye hospital a few years ago, and he was unsuccessful because of the lack of cooperation of his confrères. He believed that a society must be established for the prevention of blindness in New York City, with branches in every prominent city in the State.

Dr. L. Bolton Bangs of New York referred to the educational propaganda that all should engage in, regarding not only eye conditions, but dangers from other sources, especially syphilis and gonorrhea. It might be all right to enact laws to compel midwives and obstetricians to make use of prophylaxis, but how about, he asked, the sources of infection or contagion? How about the infected husband? These questions pertained not alone to the moral side, but to the economic as well, and they were questions, therefore, with which the State and society might well concern themselves.

A Plea for New Methods for the Prevention of Blindness.—Dr. Lucien Howe of Buffalo read this paper, the plan of which was (1) to show that ophthalmia of infancy was the most important cause of blindness, and what that meant to the State or the United States; (2) to show that from data thus far obtained the best preventative of this disease was a 2 per cent. solution of silver nitrate (the Credé method); (3) to show that more recently there had been furnished several other silver compounds; some of them were said to have the advantages of silver nitrate without its disadvantages; most of them probably were overestimated as germicides, and concerning all of them there was a vast amount of ignorance; (4) obstetricians and not oculists were the practitioners who could best decide as to the value of any of these drugs as prophylactics; (5) the plea was to obstetricians to test the value of these various compounds of silver in a large series of cases in order to decide what superiority anyone might present over silver nitrate. This could be done (*a*) by obstetricians who were in attendance at large hospitals; (*b*) by collective investigations of those in charge of smaller hospitals; (*c*) by collective investigations by members of obstetrical societies or members of county societies. He closed his paper by emphasizing the advantages that would accrue from these investigations.

Chloroma, with Special Reference to the Ocular Symptoms.—Drs. C. S. Merrill and A. J. Bedell of Albany reported the case of a patient with double exophthalmos, orbital tumors, leukemic blood, and rapid emaciation, terminating in death. Photographs were shown and the history, with the pathological report of the tumor mass removed during life, was given. They also presented a collection of statistics of ocular involvement in cases of chloroma.

The Pathology of Nontuberculous Joint Infections.—Dr. E. H. Nichols of Boston read this paper. He spoke of a series of changes affecting joints in the young or old, in one or many joints, causing suffering or loss of function. He classified them into the following types: (1) Serous; (2) ulcerative; (3) joint tending to become ankylosed; (4) joint showing tendency to formation of new bone; (5) fungous type with overgrowth of membrane and papillomatous growth extending in cavity, which might entirely fill the joint. In the treatment of the serous type it was desirable to find the original cause. In the majority of cases these cases could be cured by operation. In the treatment of the ulcerative type, moderate use and increasing the circulation by massage, etc. This applied to the fourth type.

Pneumococcus and Typhoid Infections.—Dr. Roswell Park of Buffalo read this paper. He first gave some historical data. There were two or three ways in which joint affections occurred. First, primarily, the purely toxic syno-

vitis; secondly, the embolic or truly septic form. Of typhoid joint affections, there may be the mono- or polyarticular forms. Typhoid complications may occur in the spine, or even in temporo-maxillary articulation. It appears at times insidiously. Complications of typhoid not painful; if due to pneumococcus it is painful. Attention was called to a peculiar position assumed by patient from hip involvement. It was rather startling to find a hip dislocated without known cause. These cases should be handled with great care. A joint already compromised will be dislocated with very little applied force. A large number of cases occur. Typhoid joint complications were not so infrequent as believed. He called attention to the possibilities of these cases. In pneumonia joint complications the conditions were not so greatly different. Some cases occurred early in pneumonia, with very serious complications. A doctor in Liverpool collected 31 cases, of which 24 died. They might be polyarticular. There was a furious outset, with more serious complications, and these cases were exceedingly painful.

The Symptoms and Diagnosis of Syphilitic and Gonorrheal Affections of the Joints.—Dr. Reginald H. Sayre of New York said that in all probability many syphilitic joints were not recognized as such, being mistaken for tuberculosis, rickets, scurvy, and other diseases. He described the different varieties of lesions found in hereditary and acquired syphilis. As aids in diagnosis there was the presence of discharge and there was a history of present or prior attacks shortly antedating occurrence of joint symptoms. He told of microscopical examination of fluid from the joint. The administration of antisyphilitic treatment which was followed by a cure did not mean the patient was syphilitic; many cases might get well in spite of, as well as in consequence of, treatment when not syphilitic. Gonorrheal synovitis might be primary or secondary. The spine might be the seat of gonorrheal inflammation. Such cases might be diagnosed and even cured by injections of antigonorrheal serum.

Staphylococcus and Streptococcus Joint Infections.—Dr. Lucius Hotchkiss of New York read this paper. The acute forms of joint infection came quite as frequently under the care of the general practitioner and surgeon as of the orthopedist, and formed a group of cases of the greatest importance. He emphasized the importance of early diagnosis. There was a tendency to classify all acute joint inflammations as rheumatism, a fruitful source of danger in pyogenic joint infections. He gave the general diagnostic features of the whole group, and special features as applied to different articulations. There was the necessity of exploratory punctures and bacteriological study, in order to make the diagnosis with greater certainty, and to provide the patient early and appropriate treatment. Accurate and early diagnoses were the basis of all rational treatment.

Diagnosis and Symptoms of the Rheumatoid Diseases.—Dr. R. R. Fitch of Rochester read this paper. He followed the nomenclature proposed by Dr. Goldthwait of Boston. There were four common types of nontuberculous joint disease, viz., (1) atrophic arthritis; (2) hypertrophic arthritis; (3) chronic villous arthritis; (4) infectious arthritis. He considered only the first three types. The prevention of, and relief from nontuberculous diseases was a problem not easily solved, but the division of such diseases into distinct types was the first step toward rational therapeutics.

The Mechanical Treatment of Nontuberculous Joint Infections.—Dr. Henry Ling Taylor of New York read this paper. He said that the value of mechanical treatment of nontuberculous affections was not fully appreciated by the medical profession, because as ordinarily practised it was often ineffective. The fear of atrophy and ankylosis was groundless. Joint pressure or motion, or both, was injurious in the active stages of joint infections, and might be controlled by splints and apparatus with or without crutches, or recumbency, according to the indications. Adequate and timely mechanical control promptly relieved pain, allayed the irritation, prevented deformity, and favored recovery, except in active suppuration, and in those cases where the original focus, or general infection, was of primary importance. After the irritation had subsided, vibration, massage, and movements, active, passive, or forced, might be required to increase motion. If from imperfect management deformity remained, it could be readily corrected by mechanical or surgical means. The properly adopted mechanical treatment was the main reliance in most cases of infectious arthritis, and when thoroughly and intelligently applied it gave perfectly satisfactory results.

Operative Treatment of Nontuberculous Joint Affections.—Dr. Walter Wood of Brooklyn considered this part of the symposium. He took up the topics, "When to Operate; Why Operation Was Delayed." He gave the results to be obtained by early operation. He told of the methods useful in draining ankle, knee, elbow, and shoulder joints.

The Medical Department of New York State Library.—Dr. Albert Vander Veer of Albany said that of the many factors entering into the advances that had been made in medicine and surgery during the past two decades that of medical libraries held a most important position. Through their aid many members of the profession had had access to literature bearing upon every conceivable subject in medicine that otherwise would have been denied them. One great value of these libraries had been in completing the sets of medical journals, and this branch of the work, through exchanges and gifts from the libraries of deceased members of the profession, had been accomplished at a comparatively small expense. The procuring and preservation of rare volumes and of a large number of reprints that were constantly accumulating had proven of inestimable value. Repetition in writing upon the same subject had been avoided to a certain extent. Writers had been able to note just what had been said upon the various subjects in the past, and this knowledge had also been of the greatest value. New York State was particularly fortunate in having several of these important centers possessing medical libraries. With the completion of the State Educational Building at Albany it was very desirable that this interest should be continued, for the success of medical work could here be brought about with a minimum expense to the State and could be administered to the advancement of the medical profession in a manner that must result in great good to the public.

State Aid for Medical Libraries.—Dr. Smith Baker of Utica read this paper. According to the Medical Directory of the State of New York, there were at present in the State some sixteen incorporated medical libraries, with an additional one at Utica but just started, and the New York State Medical Library at Albany. Tabulating the number of volumes in the ten libraries heard from, they found a grand total of about 180,080 volumes. For the purchase of new books and periodicals there was used annually a sum derived from private and corporate sources of something under eleven thousand dollars, while the State contributed additionally to the University of Buffalo for a like purpose the magnificent sum of just $100. Without taking these figures as accurate totals, they would yet suffice well enough to bring to view and illustrate three important facts. 1. That there were now but a very few public medical libraries in the State, when there might be and ought to be many more. Why this was so they need not stop to discuss, although the fact itself, upon careful consideration, was a matter for greater regret than any sort of cursory notice justified. 2. That the libraries now in existence, with the exception of that of the State, located in Albany, and the $100 appropriated to the University of Buffalo, had been paid for originally and were now maintained by funds notice justified. 2. That the libraries now in existence, without help from the State beyond certain annual reports and the like. This, too, was a significant revelation to one who

had never before investigated or given thought to the subject. 3. That for the purchase of books, periodicals, etc., there was expended in the whole State a sum total of over $11,000 annually, and yet of this amount over $9,000 came from the same private sources as the original provision. When this was thought of in connection with the $2,000 spent by the State for a like purpose, it became a third revelation of equal or greater significance than the others. It seemed strange that medical men outside of Albany must rely upon themselves alone, or upon some arrangement with the State Library, for assistance in their professional literary extremity. Practically, to the vast majority of the profession of this State, the books in the State Medical Library were not available, and never would be; for even the loan of books which might be secured could only be for temporary purposes, and, generally speaking, practitioners found this arrangement too bungling and unsatisfactory to be of much use. He saw no reason why, when it came to instituting here and there little collections of books and periodicals for the daily inspiration and instruction of the local profession, they should not urge upon the State with all their might the absolute justice of its lending a very material and otherwise encouraging hand, especially wherever the profession itself should take the proper initiative, and thus do its part in commanding rightful recognition and respect.

The Physiological Therapy of Sanatorium Treatment.—Dr. Beverly O. Kinnear of Clifton Springs read this paper. He gave a concise statement of what a sanatorium was upon a large scale, and the diseases most frequently met with in large sanatoria. He also treated of the advantages of sanatorium treatment over those usually employed in the large cities, but chiefly in reference to the chronic forms of disease. He called attention to the modern sanatorium treatments and their effects upon excretion and secretion, upon the cerebrospinal centers and system, upon the systemic circulation, the sympathetic nervous system, upon arterial hypertension, not due to known organic lesions. He reported special illustrative cases and gave an exposition of why the successful results were obtained. He specially emphasized the importance of a careful study of the sympathetic nervous system.

Syphilitic Lesions of the Eyelids, with Reports of Cases.—Dr. Frank Judson Parker of New York read this paper. He said that the appendages of the eyes might be the seat of any or all of the lesions of the different stages of syphilis. The most common were the exanthemata which varied as in other parts of the body; on the eyelids they were of rapid growth, and they might occur at any age and period of the infection. Inflammation and swelling of the tarsal cartilage was nearly always syphilitic. Chancre of the eyelids was among the rare forms of extragenital infection, and might be easily mistaken for lupus, epithelioma, a suppurating hordeolum, or chalazion. In the eye clinics of the Manhattan Eye, Ear and Throat Hospital, of 33,960 eye cases treated in two years, five were diagnosed as chancre of the eyelid. This condition was much more common in males, and the right eye was the more liable to infection. Ocular infection was frequently due to accidental causes. Physicians became infected by the coughing of patients while the throat was being examined; Fournier had reported five such cases that came under his personal observation. The use of public towels, sponges, etc., was a frequent cause of chancre of the eyelids, the tender epithelium of the edge of the lids being easily abraded by rubbing. The chancre most frequently occurred on the conjunctival surface and rapidly involved the entire lid. Enlargement of the preauricular or the submaxillary glands always occurred in chancre of the eyelids. The prognosis was good, and, if treated early, there was no destruction of tissue or deformity. Two cases were reported, one a syphilitic granuloma of the lower lid, the other a chancre on the margin of the upper eyelid.

The Spirochæta Pallida.—Dr. James Ewing of New York spoke on this subject, illustrating his remarks with a lantern slide demonstration.

Symposium on Cancer.—The remaining hours of the session were taken up with a discussion on cancer.

A Synopsis of the Work of the Buffalo State Laboratory During the Past Eight Years, Retrospective and Prospective.—Dr. Roswell Park of Buffalo gave a brief review of the history of the State Cancer Laboratory at Buffalo and the work accomplished. He told of the difficulties in securing State cooperation, and of the impossibility of turning out results to order. He gave comparisons of its work with that accomplished elsewhere, and he made brief references to Cancer Laboratories under foreign governmental auspices. He indicated what the future might reveal, and what might be accomplished by continued work in the same direction.

Parasitism and Infection—The Etiology of Cancer in the Light of Recent Laboratory Advances.—Dr. Harvey R. Gaylord of Buffalo called attention to the observations made in the New York State Cancer Laboratory where a cage had become infected from sarcoma rats and in which in the course of two years three cases of sarcoma had developed in eight rats thus exposed. These cases developed a year apart and the cage was known to have been infected for a period of three years. Heredity played no part in these occurrences. He further described an infected cage which was purchased from a dealer and brought to the State Cancer Laboratory, out of which sixty or more tumor mice had been taken in the course of three years by the dealer, and in which five cases of cancer had developed after the cage was brought to the State Cancer Laboratory. With these facts so strongly indicating the infectiousness and contagiousness of cancer, a typical small spirochete was to be found in all the transplanted tumors thus far examined. Up to date some twenty odd mouse tumors had been cut, giving positive results, using the silver method of Levaditi. In the more virulent tumors the organisms were present in great numbers distributed in the consecutive tissues around the margins of the tumors and in the connective tissue stroma. They were occasionally found between the epithelial cells and were known to have been present in one of the strains in 1905, when they were first detected in large numbers in vacuoles in the epithelial cells of one of the transplanted tumors. They were now apparently constantly present in three separate strains of transplanted tumors, one being the Jensen tumor and two tumors of American origin. The presence of these organisms was interesting from the fact that they had constantly accompanied these transplanted tumors for so long a time and that in preparations stained in the ordinary way there were no alterations in the histology of the tumors which could be deliberately attributed to the presence of the spirochete. Having found the organisms over twenty times consecutively by the Levaditi method, three primary mouse tumors which did not communicate with the air, being entirely enclosed and movable beneath the skin, of small size, were removed aseptically and carefully sectioned after impregnation with silver. In two of these tumors the impregnation method was obviously not successful. In one of these occasional badly fixed organisms could be found. The condition of the tissue in the other made it obvious that the method was not successful. The third tumor examined was properly impregnated and contained large numbers of organisms scattered through the tumor, but most plentiful in the actively growing portions. Here they were found among the epithelial cells, usually surrounded by small vacuoles. They were invariably present in the larger cysts of the tumor, which was an adenocarcinoma. They were characteristic in appearance, from 4 to 6 microns long, with very closely round, abrupt gyrations, each measuring not over one-half a micromillimeter. Involution forms were not infrequent and fields showing active phagocytosis

on the part of the epithelial cells were to be found. In these cells the organisms were found curled into rings or irregular masses, making inclusions such as had already been described by Prowazek for the organism producing spirochetosis in the fowl (Brazil). By careful examination of the transplanted tumors this organism could be seen in the fresh state. It was very small, very actively motile, moving rapidly forward and backward. It occasionally came to rest, when the gyrations could be seen, but its dimensions were so minute that neither flagella nor an undulating membrane could be seen. All attempts to stain this organism with Giemsa or other aniline stains had been fruitless. In this respect it appeared to differ from similar organisms seen in ulcerating tumors described by Loewenthal and Borrel in unulcerated mouse tumors in the Pasteur Institute, one from Ehrlich's laboratory. Similar organisms had been found by Freudenthal in an unulcerated human cancer. Loewenthal and Ewing and Beebe had found them in smears from dog tumors, and there was every reason to believe that this organism or similar organisms were widely distributed. In connection with the possibility of these organisms having an etiological relation to these tumors, Dr. Gaylord pointed out that the recent work of Fischer, showing that Scarlet R would induce proliferation of the epidermal epithelium of the rabbit's ear when injected beneath the skin, might afford a possible explanation of how an organism like a spirochete could induce proliferation through the medium of some toxic substance. The distribution around the periphery of the transplanted tumors of the organisms, in the light of Fischer's work, was suggestive, and the evidences of phagocytosis on the part of the epithelial cells would explain how the organism could be transported by the cells and continue the irritation necessary to the development of metastases. The reader suggested that the task before them consisted in careful examination of uncontaminated human tumors for the purpose of determining with what regularity these or similar organisms were present, bearing in mind that in the light of Fischer's work very few organisms could produce extensive proliferation, and that inasmuch as Scarlet R affected only the epithelium of the epidermis in the rabbit and had no effect upon the epithelium of other regions in the rabbit, it was highly probable that they were dealing with a large group of organisms, each of which produced a toxin, or, as Fischer called it, an attraxin, for certain kinds of epithelium. It was, therefore, not necessary to look for a specific organism, but rather an organism of a specific group, and it must be borne in mind that there were difficulties in distinguishing between the different spirochetes thus far described.

Experimental Research in Connection with the Transplantation of Carcinoma in Mice.—Dr. H. G. A. Clowes of Buffalo presented this communication, which was a summary of his remarks made at Cleveland January 11, 1907. He said that experimental research in cancer had received an enormous stimulus in the course of the last few years through the discovery of the ease with which mouse tumors might be transplanted from one individual to another. A large number of primary tumors had come into the possession of the New York State Cancer Laboratory in the course of the last three years. During this period numerous experiments had been carried out in this institution, having in view the determination of the exact conditions under which physical and chemical agents inhibit the development of rapidly proliferating tumor material, and also of the conditions under which immunity against cancer occurred. Three main types of tumor had been employed, possessed of low, of intermediate, and of extremely high virulence, respectively. In the latter series a yield of over 95 per cent. of tumors was obtained and the average period of time required for a fatal development was twenty-five days from the date of inoculation. In order that records of the experiments carried out might be rendered permanent, a system of making charted diagrams of the tumors in individual mice was adopted from the start, and owing to this system it was discovered at an early stage that a considerable number of mice recovered even after their tumors had reached considerable dimensions. The occurrence of such spontaneous recoveries was found to be most frequent in those groups inoculated with the least virulent materials and less frequent in those treated with the highly virulent, rapidly growing tumor referred to above. The subsequent inoculation of mice which had recovered spontaneously with tumors of an equal or even greater virulence than that first employed demonstrated that the animals in question were possessed of a marked immunity, practically no tumors occurring in such cases, while control animals showed a normal percentage. The tumor cells had been shown to be very resistant to the action of chemicals, withstanding the treatment with mercuric chloride, potassium cyanide and other bodies of this nature, of a concentration sufficiently great to destroy bacteria. They also showed a considerable resistance when inoculated at relatively high temperatures, ranging from 40° C. to 45° C.; in fact, tumors possessed of a very low grade of virulence might be stimulated to increased activity by inoculation at temperatures ranging from 38° C. to 41° C. for half an hour previous to inoculation. Evidence of the existence of immunity against cancer was presented as follows: (1) The occurrence of spontaneous recovery from true cancer. (2) Such spontaneous recoveries were not reinoculable. (3) The reduced percentage of tumors obtained on reinoculation of those mice which failed to take after the first injection of tumor material. (4) The reinoculation with highly virulent materials of mice which had been previously treated with a weak strain, which, according to Ehrlich, lead to a considerable reduction in the percentage of tumors, as compared with normal untreated mice. (5) An experiment was carried out as follows: 100 mice were inoculated in the neighborhood of the head with the virulent tumor strain referred to above, with the result that over 95 per cent. showed tumors of considerable size in ten to fourteen days, at which time they were reinoculated in the region of the tail with tumor strains of an equal or greater virulence than that originally employed, while in all cases a series of unused mice were employed as control. After a further period of ten days it was found that large tumors had developed in all the control animals, but that those animals in which tumors were already developed before the second inoculation showed relatively little signs of tumor development at the second point of inoculation. This experiment, together with the fact that metastases seldom occurred in the early stages of tumor development in mice, would indicate the probable existence of antibodies in the serum antagonistic to development of isolated tumor cells. (6) The serum of spontaneously recovered mice appeared to exert a slight effect upon growing tumors when injected directly and also to interfere to a certain extent with the development of tumor cells when admixed with the latter previous to inoculation. In their experience no immunity had so far been obtained by means of inanimate materials as, for example, tumor cells destroyed by heat, tumor cells treated with an overdose of chemicals, and nucleoproteids extracted from virulent tumors following the procedure adopted by Beebe in his work on exophthalmic goiter. The evidence so far obtained might be said to harmonize most readily with the parasitic theory of cancer. Ehrlich's recently advanced theory that cancer cells proliferate in virtue of their possessing side chains having greater affinity for food than those of the normal body cells was perfectly compatible with the parasitic theory, providing the parasite or its excretory products be looked upon as the *x*-body of Ehrlich playing the part of a stimulating or sensitizing agent. In conclusion he said that it should be stated that all the evidence thus far obtained of the existence of an immunity against cancer would indicate that that immunity was brought about by

a process analogous to vaccination, the individual infected with an attenuated or mild form of the disease from which it recovered being found on subsequent inoculation to possess an immunity against cancer strains of equal or even greater virulence.

Cancer as a Biological Problem.—Dr. Gary N. Calkins of New York discussed the question from this point of view, illustrating his remarks with a lantern-slide demonstration and the exhibition of specimens.

Wednesday, January 30—Third Day.

Sahli's Desmoid Reaction.—Dr. H. C. Carey of Troy read this paper. After describing the method employed by Sahli, he reported upon the work done by him in the use of capsules, tied at either end with catgut. The capsules contained methylene blue, which he considered to be superior to iodine or salicylic acid. When the catgut was dissolved by the acids in the stomach, this liberated the methylene blue, and its presence was noted by an examination of the urine. This method was of value in determining the digestive sufficiency of the gastric juice and its ability to digest a meal with which the capsule was given. This method was not at all suited to differentiate the functional disorders and did not take the place of the stomach tube and test breakfast.

A New Disease; History, Symptoms, and Pathology of a Hitherto Unreported Lesion.—Dr. Henry P. De Forest of New York read this paper. He reported the case of a man with inflammation of the thoracic duct. At Autopsy all the organs were found to be normal except the kidneys and the liver. On careful search a mass the size of a bologna sausage was found. In the center of it was an abscess cavity, which easily admitted the finger. The mesenteric glands were greatly enlarged. This mass was at the receptículum chyli, and the condition extended from there up to the jugular vein. Several masses were noted, all distinctly nodulated, and all the size of a finger. The pus could be squeezed from the thoracic duct into the jugular vein. The clinical history showed that there was first a ptomain poisoning from shell fish. Then aggravated symptoms followed the eating of cold storage duck, greatly lessening the resistance of the intestines, therefore allowing ptomains to gain access to the system and bacteria as well, the pyocyaneus showing the blue pus. When each valve was overcome there would be a chill, and, when finally the abscess perforated into the jugular vein, the symptoms of septicemia developed as shown in last week of life.

Blood Pressure Study; Some Unexpected Revelations.—Dr. Henry L. Elsner of Syracuse read this paper. He spoke of the importance of arterial tension for diagnostic and therapeutic purposes. He did not underestimate the fact that we were not always able to determine the vascular tension of man with absolute precision, but held that the sphygmomanometer of to-day gave sufficiently accurate information of systolic, diastolic, and pulse pressure to justify safe conclusions. A large part of the paper was devoted to the consideration of chronic arterial hypertension and the baneful results which followed unless the underlying process was controlled. Hypertension was usually a compensatory measure, and it was often a mistake to give drugs which lowered blood pressure without considering primary causes. Longevity depended on cardiovascular competence. Hypertension was usually accidentally discovered. In 600 consecutive examinations chronic arterial hypertension was present in 1¼ per cent. This gave no idea of the frequency of this condition, and the writer was certain that a larger number of cases would be discovered if an equal number of supposedly healthy individuals engaged in active pursuits between the ages of 35 and 50 were subjected to blood-pressure study. This condition of hypertension was found in the strenuous and active. Its early recognition and control were of economic importance to the State and to the nation. The rapid development of arteriosclerosis in professional men after short periods of hypertension was a depressing and alarming fact. Worry as a factor in causing hypertension was considered. It was shown by clinical experience that exophthalmic goiter was, as a rule, a disease of hypertension; that its persistency was often associated with, or led to arteriosclerosis. Diabetes was very likely to be associated with hypertension, leading to deep changes in the walls of arteries. Peritonitis and typhoid fever, with its complications, were considered, and it was demonstrated that with the former, during the early hours of its existence, blood pressure was likely to be raised. Localized peritonitis with typhoid, also the early hours following the perforation of the typhoid ulcer, were associated with rising blood pressure, a fact which was of great importance in diagnosis. The effect of drugs on blood and pulse pressure was considered and its importance demonstrated. It was shown that in spite of high blood pressure, pulse pressure might be very low; thus with the high blood pressure and low pulse pressure valuable indications for cardiac stimulation were given. The effect of filling the splanchnic vessels in the presence of pulmonary edema was considered. The use of nitroglycerine with adjuvants for this purpose was recommended in the presence of an insufficient heart with peripheral arterial obstruction and associated pulmonary edema.

The Classification of Blood Pressure Cases.—Dr. Louis Faugères Bishop of New York read this paper. It was not his intention to attempt a complete classification of circulatory diseases, all of which were dependent in their ultimate analysis upon the distribution of blood pressure, but rather to advocate that a particular set of cases, which he described as hypertonia vasorum idiopathica, had a place in such a classification. On former occasions he had classified departures from the normal in blood pressure under three principal classes, primary low arterial tension, high arterial tension, and secondary low tension. He had also described certain special cases under the name "Constitutional Low Arterial Tension," etc. He now wished to subdivide our high pressure cases into those due to nervous causes, and those due to other causes. As high arterial tension in connection with the classical cases of kidney disease had been so often described, he passed them over to go on to the description of the other type. Hypertonia vasorum idiopathica stood for a class of cases in which high arterial tension often existed, but which evidently were neither of nephritic origin, nor had their origin in changes in the blood vessels. The causes were found in changes in men's habits. The present time was characterized by overwork and worry on the part of a larger proportion of the community than formerly. Men live in a state of mental tension that we believe to be the cause of the increasing number of persons who suffer from this disorder of the circulation. The treatment of this condition must of necessity be by creation of such influence as would counteract the tendency. This was possible by the employment of drugs, which for the time being will prevent damage, but other means must be employed. It had long been known that physical exercise would prevent or postpone the breakdown that eventually follows overwork and worry. This was due to something more than the indirect general good effect of exercise on the health. It was due to the fact that there existed a muscle tone maintaining function of the central nervous system that had a close relation to the blood-vessel tone maintaining function. By bringing into healthy activity the one by exercise of the voluntary muscles, the other was favorably influenced. While this was true of ordinary use of the voluntary muscles, it seemed to be more true when resistance exercises were employed. Walking down stairs seemed to be a resistance exercise, and had undoubted value in cases of weak heart with a tendency to hypertonia. Diet was also an important element, and must usually take the form in these cases of restricting certain articles of food. Sugar and red meat could be pronounced as a matter of experience to be harmful. Red meat might have some direct influence on the tone-maintaining function of the muscles of the blood-vessels. We had

called the disease idiopathic because that is the custom when the exact causes had not been definitely traced out. There was nothing wrong in the early stages with the circulatory system. There was only something wrong with the way in which it was acting. The cure of hypertonia vasorum consisted in regulating the functional activity of the brain, heart, and blood-vessels so that they should run smoothly. In some cases this was easily accomplished, and in others only with great difficulty, but it was never accomplished by a single prescription or any other single measure. It would be just as irrational to employ a physician to cure a circulatory disorder by a single prescription as to employ an engineer to start an engine, and then dismiss him only to be employed again in case of a breakdown. The only successful treatment was by the regulation of the circulation and the gradual adjustment of measures to this end, until finally the vicious habit was broken up and the tendency to hypertonia overcome. The most valuable drugs could not be given in efficient doses, except under constant supervision. It is easy also to carry exercises too far, which at the time when they were ordered were entirely correct. Nowhere else in medicine do they come more forcibly to the consciousnses of the wrong position in which the physician was placed when he is only called upon to repair damage—in this case damage which never should have occurred.

Dr. Theodore Schott of Bad-Nauheim, Germany, after referring to the various instruments in use for determining the blood pressure, said that what was revealed by them was of little if any value without further clinical observations; it was only just one help. In the use of the instruments, these sphygmomanometers, a difference of from 30 to 40 mm. of mercury would be noted in some cases when they were applied above the level of the heart or below it and in one minute's time. High blood pressure was only a symptom, and must be combined with further observations of the case. He emphasized the point that this was only one of the signs, and nothing else.

Dr. DeLancey Rochester of Buffalo emphasized the importance of becoming an expert with one instrument, and not attempting to use many of them, and of making several observations. By the use of the sphygmomanometer he had been able to save, without doubt, some lives from perforation in typhoid fever. He called attention to the fact that nitroglycerin was very evanescent in its effects.

Dr. A. Jacobi of New York said that the New York City Health Department had collected samples of tablets of nitroglycerin from various parts of the city and from the wholesale druggists, and they found that tablets calling for a certain dose ranged from 1-100th of a grain to 1-2500th. One who used these tablets was continually in danger of getting that which was worthless.

The Criminal Lunatic: His Status and Disposition.—Dr. Robert B. Lamb, Medical Superintendent of Matteawan State Hospital, read this paper, dealing largely upon the present New York practice of dealing with the criminal insane. The different forms of commitments on criminal orders were discussed, and certain apparent defects in the prevalent system were pointed out, with remedies therefor. Dr. Lamb regretted that no legal cognizance was now taken in cases of diminished responsibility or constitutional inferiority, the old legal definition of insanity being the only interpretation generally permitted in the Courts. The customs of permitting lay juries to pass upon the mental condition of criminal lunatics, and of constituting commissions of lunacy with a medical minority, were strongly condemned. Mention was made of the general attention this special line of work was now attracting, both the bar and medical societies recognizing the need of betterment of present conditions. Now was the movement active in this country, since Dr. Lamb stated that his paper was suggested by a series of inquiries made by the authorities of Germany.

The Visions of Mary Czajka.—Dr Francis E. Fronczak, Assistant Health Officer of Buffalo, presented this communication by title. A nineteen-year-old Polish girl gained a reputation of being able to foretell the future, and to communicate directly with heaven and the saints. Great crowds visited her at certain hours while she had these "visions." She would sit in a chair, suddenly stiffen out, become perfectly unconscious of all her surroundings, and in a few seconds repeat slowly what the Blessed Virgin or the saints would tell her. She was held in great admiration until after a thorough medical examination, when she was declared to be suffering from hysteria and exaggerated hallucinations. At present only a few people saw her, and she seldom had the "visions."

The Importance of the Routine Examination of the Urine for Indican.—Dr Joseph Day Olin of Watertown presented this communication, in which he emphasized the importance of a routine test for indican, from the standpoint of its significance and frequency of occurrence in some of the more common ailments.

Underfeeding and Its Associated Ills.—Dr Dudley D. Roberts of Brooklyn read this paper, in which he said that the determination of underfeeding was to be made only by the effect of an increased diet. Certain suggestive criteria were to be found in the physical condition, the symptomatology and accurate determination of the food habits, and this determination could only be reached by painstaking cross-examination of the patient. He considered the fundamental causes of underfeeding, the saving of time and money, the loss of appetite, and the subjective disturbances of digestion. Among the clinical types were the gastric, the intestinal, the anemic, and the nervous. He told of the cure in forced feeding, and the moral and suggestive aids.

Dr. Heinrich Stern of New York stated that when speaking of underfeeding we should at first know who was underfed. Was that individual underfed who had but a few pounds in body weight? Was not that individual to be considered as underfed who could not perform his accustomed amount of work without exertion, and who had deteriorated in so far as his specific gravity, his corporeal density had declined? Might not the supposed loss of absolute weight be a physiological phenomenon, might the individual not have been too heavy for his various digestive and assimilative organs? Dr. Stern said that he had pointed out, some years ago, that it was not the absolute weight alone which determined a man's obesity, but his specific weight, his body-density. Accordingly, he demonstrated four different types of obesity: (1) That characterized by increased body-density, when one had a surplus of muscle tissue; (2) the type in which the specific gravity remained about stationary, when one had an increase of both muscle and fat tissues; (3) the type when one had loss of body albumin, but increase of fat structures, when one had a decrease of specific gravity; (4) the type in which loss of body albumin was going hand in hand with increase of fat and water, when the specific gravity of the organism was at the lowest point. We had to reckon with an analogous condition in the underfed. It would lead him too far, Dr. Stern continued, to dwell at length on these points on this occasion. He had frequently committed his thoughts and experiences to print. Suffice it, he said, that we must first know whether an individual was underfed before we attempted to cure him. There was a cardinal factor always to be remembered, namely, that most so-called underfed individuals ingested sufficient material, but that they did not utilize it properly. That is to say, they filled up the stomach and intestines with a great deal of food, but their intestinal functions were deficient in so far as they did not suffice to elaborate properly the real nutrients from the crude ingesta, and that assimilation was not carried on in a physiologically sufficient manner. These individuals might starve even if their stomachs were loaded with food. In his opinion, all treatment of the underfed lay in the treatment of the underlying deficiency of the intestinal functions. This must

be attended to first, before one could think of upbuilding the organism. All feeding, without this preliminary treatment, he continued, would be useless. In overcoming the marasmus of children, it was specially the fat which was not absorbed. In such instances, fat substances which did not yield fatty acids of low melting degrees, should be prescribed. For infants, nothing, Dr. Stern concluded, was worse than the fat of cow's milk, which contained 10 per cent. and more of volatile fatty acids, which were liable to be converted into acetone substances; and nothing better than the uncooked yolk of the hen's egg, which yielded only fatty acids of high melting power.

The Technique of the Ablation of the Breast.—Dr. Parker Syms of New York read this paper and said that the modern methods of removing cancer of the breast were far in advance of the older ones, and, while much more extensive and radical, they might be done so as to cause less shock and risk to the patient. The death rate from the operation was very low, and the final results as to permanent cure were far better than under the old régime. Dr. Syms preferred the method of Dr. Willy Meyer to all others. It was anatomical, never atypical, and, if properly done, was bloodless. The blood-vessels were all cut at their trunks and not at their small branches. One half a dozen to a dozen artery clamps were ample. The method did not consume too much time, for one hour to one hour and a quarter should complete it. The carcinoma was not cut into, the lymphatics and veins were removed from above downwards and not in the direction of their current. There should not be any shock, and the patient might be out of bed within forty-eight hours. Death from the operation should be very rare. Motion and proper function of the arm were not interfered with and the blood circulation of the arm was seldom impaired. Dr. Syms regarded this method of operating as one of the greatest advances in modern surgery.

Dr. Bonner of Brooklyn said that during the last five months he had operated upon three cases of carcinoma of the breast, doing the operation according to the method of Dr. Meyer. All were in the early stages and well nourished. He thought it was a mistake in the technique to permit the oozing to settle down without permitting drainage, which might occur in the method pursued by Dr. Syms. Grafting was better than cicatrization of the wound, because it permitted of better motion afterwards.

Dr. Joseph D. Bryant said that the principles involved in the operation were most profound and of significant benefit, contemplating the removal widely of the diseased tissues and all the tisuses that were likely to become involved; but he wished to supplement what had been stated by saying that operative procedures should be continued when there were the slightest manifestations of return; in other words, the disease should be fought to a finish.

Dr. Gregor of Watertown said that he always carefully packed the axilla and used rubber drainage, which remained in one week, and the patient was discharged as a rule on the tenth or twelfth day.

Dr. Syms said that he would drain the posterior space if he was not absolutely sure that all oozing had ceased, and that he drained more than one-half of his cases. The question of grafting must be left to the decision of the individual operator. The supplementary incision of Warren, or better yet, that of Jackson, would provide a flap which could be so slid to close the defect made.

Surgical Treatment of Goiter.—Dr. Martin B. Tinker of Ithaca read this paper. He said the relatively infrequent occurrence of goiter in America partly accounted for lack of acceptance of operative treatment. Sudden deaths from appendicitis or extrauterine pregnancy aroused the public and profession to realize the necessity for radical measures, but the slow development of alarming symptoms of goiter had made all concerned ready to temporize with goiter. In Switzerland goiter operations were more common than appendectomies in this country and less dangerous. The term goiter was used to include various tumors, benign and malignant as well as simple, hypertrophic and exophthalmic goiter. Little that was definite was known as to the etiology of goiter; it was more common in women at puberty or pregnancy, sometimes followed nervous strain, and was far more prevalent in mountainous districts. The symptomatology was briefly discussed; pressure symptoms occurred with all large tumors, and when difficulty in breathing and swallowing, changed voice, cough, or even bloody expectoration occurred, with small tumors, malignancy should be suspected. In operating local anesthesia was advised; a low transverse incision avoided visible scar; placing the incision between the branches of distribution of the superficial cervical and supraclavicular nerves made local anesthesia simple; the sternothyroid and thyroid group of muscles were divided high to avoid injuring the nerve supply; arteries were secured first, then all veins; the recurrent laryngeal was carefully avoided. Charts and dissections illustrating the anatomy were presented. Statistics of prominent internists showed a mortality much higher than the operative mortality of experienced surgeons. Personal experience without deaths and with highly satisfactory results was quoted. Operation should be urged after thorough trial of palliative measures had failed to give relief.

Clinical Features and Operative Treatment of Thyroid Affections.—Dr. George E. Beilby of Albany presented this paper, in which he made a classification of the diseases of the thyroid gland, clinical features, and diagnosis. He gave reports of illustrative cases and discussed the operative technique, with special reference to the management of Grave's Disease, or exophthalmic hypertrophy.

Dr. Joseph C. Bloodgood of Baltimore, Md., said that the good results of the treatment of exophthalmic goiter depended more upon the early stage of the disease when it was begun than upon perhaps any particular method of operation. If one expected to get permanent results by the removal of one-half or two-thirds of the gland, it must be done in the early stage. A few years ago it was noted that after operation the patients improved very rapidly and the results were supposed to be beautiful; but after a few months it remained stationary. In some cases operated upon late there was no improvement, but recurrences. With regard to the so-called aberrant tumors of the neck, frequently they cut down upon them, removed them, and later the tumor proved to be made up of thyroid tissue, and the surgeon was surprised to find myxedema develop. In eight per cent. of such cases myxedema had developed. As far as malignant growths of the thyroid were concerned, he had never known of a cure after the picture of malignaney had developed.

Some Recent Clinical Observations in Intestinal Obstruction, Both Acute and Chronic, with Demonstration of Specimens and Illustrations.—Dr. Joseph C. Bloodgood of Baltimore addressed the Society on this topic. Intestinal obstructions was not a common disease. In Dr. Halsted's clinic only 106 cases were on record. In a large clinic in Germany they only averaged 70 during the last 20 years. As a rule the general practitioner saw these patients first, and it should be impressed upon them that the mortality of intestinal obstruction was very great if operation was delayed more than 48 hours. The mortality of operation 48 hours after the onset was about 70 per cent.; within 24 hours the number of recoveries was 70 per cent. Therefore, the results were a matter of time. The question arose as to the possibility of recognizing obstruction of the intestine within that limit. He said it was possible if certain rules, which were difficult

to follow, were followed. Every individual suffering from abdominal pain might be developing intestinal obstruction; yet out of 100 so suffering only two or three would develop it. In looking over his cases his experience taught him that any patient who had pain enough to require the use of morphine, if the pain was not in the region of the kidney or gall-bladder, and not followed in a few hours by watery stools, might be presenting the symptoms of a beginning obstruction of some form. According to the pathology he divided these cases into two groups: first, strangulation in which the lumen was not only obstructed, but the circulation interfered with as well, and, secondly, obduration, in which the lumen was blocked, but with no interference with the circulation. In the first, the symptoms were more acute, an immediate operation was more demanded, and the diagnosis easier. In the second, the symptoms were less acute, the importance of early operation was not so great, but unfortunately the diagnosis was more difficult. The cause of abdominal pain was not yet known. Whenever a patient suffered acutely from abdominal pain, initial vomiting, and shock, he advised against the giving of morphine. Give no treatment except a rectal enemata and wash out the stomach.

Toxic Nephritis Dependent Upon Surgical Conditions.—Dr. NATHAN JACOBSON of Syracuse read this paper. He presented three cases. The first one was presumably of staphylococcus infection in which the patient suffered from septic endocarditis as well as from nephritis; the second was a case of intestinal obstruction without septic disturbance of any kind, and in which in consequence of the complete arrest of intestinal function a very serious and all but fatal form of nephritis was awakened; the third was one in which there was complicating gallstone disease, a subacute pancreatitis, and in consequence of the disturbance of the secretory function of this gland a toxic condition was aroused, causing not only a nephritis, but also glycosuria. In each of these three cases, after the removal of the causal condition all evidences of renal disease disappeared.

The Surgery of Foreign Bodies in the Respiratory Tract.—Dr. W. G. MACDONALD of Albany presented this communication. He said that foreign bodies aspirated into the respiratory tract would always be an important chapter in emergency surgery so long as infants were permitted and adults voluntarily used their mouths as storehouses for an infinite variety of foreign bodies. Until very recently the mortality associated with this accident was very great, being from 15 to 27 per cent. in operated cases and from 23 per cent. to 51 per cent. in the non-operated cases. The material improvement in the mortality might be attributed to the greatly increased skill of those who were especially interested in the field of the respiratory organs. The discovery and universal employment of the Roentgen ray for diagnostic purposes, the inventions in mechanism of the direct inspection of the larynx, trachea, and bronchi, and the recent development in technique had conspired to make diagnosis more certain and operative technique more simple, sure, and successful. Dr. Macdonald then referred to the striking features which presented in fourteen operative and two nonoperative cases and gave a cursory review of the literature. A very striking feature lay in the size of the bodies aspirated. In one case was a hatpin, fourteen cm. long and having a glass head more than one centimeter in diameter; artificial tooth plates having as many as four teeth had been aspirated, etc. From his clinical experience Dr. Macdonald said that the normal plan of treatment of foreign bodies lodged in the deep trachea or bronchi was a preliminary inferior tracheotomy. If the body was mobile, a wide tracheal incision, well held open, would lead to the expulsion through the violent attacks of coughing. If the body was fixed in the bronchus or the lower trachea the bronschoscopem, using a shorter tube, might be employed. With bodies fixed deep within the trachea there was failure to secure their removal at the primary stage in about ten per cent. of the cases. Under such circumstances the edges of the tracheal wound should be sewed to the skin, a large tube introduced, and the operation ended.

Foreign Bodies in the Uterus.—Dr. B. S. TALMEY of New York read this paper. He said that the occurrence of foreign bodies in the uterus was relatively rare, and hence every case should be reported. The cases might be divided into three classes as follows: (1) Those introduced into the uterus for the purpose of emptying the contents of conception; (2) those introduced into the uterus by accident; (3) those introduced for onanistic purposes. To the latter class belonged the first case, a girl, 19 years old, in whom was found a hairpin sticking in the cervical canal. The second case belonged to the first class, where a bougie 22 centimeters long was introduced into the uterus, perforating the same. The laparotomy showed the bougie to be buried under the loops of the intestine. Dr. Talmey said that, although these cases were rare, still it would be of use to make the practitioner familiar with the question.

Further Observations Upon the Treatment of Diffuse Septic Peritonitis Following Appendicitis, with a Report of One Hundred and Forty-five Cases Treated by the Elevated Head and Trunk Positions.—Dr. RUSSELL S. FOWLER of Brooklyn read this paper, and in conclusion stated the salient points in the treatment of these cases were as follows: 1. A small incision and the avoidance of eventration. 2. Thorough cleansing of the primary focus of infection and removal of the appendix. 3. Vacuation and cleansing of all accessory abscess cavities and the pelvis before washing out the peritoneal cavity. 4. A rapid systemic flushing of the peritoneal cavity with hot saline. 5. The continuance of the saline flushing until the sutures were placed, and for the most part tied. 6. The provision of proper drainage for the pelvis, either by means of a large glass tube containing a capillary drainage strip emerging through the lower angle of the wound, or in females by a large caliber rubber tube filled with wicking passed through a posterior colpotomy incision. 7. The drainage of accessory abscess cavities with gauze or wicking. 8. The elevation of the head of the bed to accelerate the drainage of septic fluid into the pelvis, whence it could be removed through the tube, or in case of vaginal drainage find a ready exit. He stated that there were a few cases of diffuse septic peritonitis which might be safely closed without drainage.

A New Operation for the Radical Cure of Femoral Hernia.—Dr. A. V. MOSCHCOWITZ of New York presented this paper. In his introductory remarks he reviewed the large number of operations that had been done hitherto, and pointed out their shortcomings. These shortcomings were due to the fact that they did not permit a high closure of the peritoneum, and that they did not close up the internal femoral ring. In order to obviate these faults, he operated through an incision in the inguinal region, and converted the femoral into a direct inguinal hernia. The sac was then ligated or sutured in the usual manner, which could be readily done under the guidance of the eye, and so high up as to obviate the formation of a peritoneal dimple. The internal femoral ring was then closed by suturing Poupart's ligament to Cooper's ligament and to the periosteum of the pubic bone. The subsequent steps of the operation were those of the Bassini operation for inguinal hernia. Dr. Moschowitz then pointed out the ease and facility with which the operation could be done, and the other advantages, particularly [illegible] of strangulation. He said he had operated [illegible] operated upon twenty cases, the first case having been operated on in May, 1905. All the cases had been under continuous observation, and the [illegible] of a recurrence.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS FOR THE STATE OF TEXAS.

Galveston, June 6, 17, and 18, 1906.

Each applicant will answer ten questions of his own selection in each of the following papers:

ANATOMY.

1. Describe the fifth cervical vertebra.
2. Give the origin, insertion, and action of the pectoralis major muscle.
3. Name the muscles which supply the tongue and give their function.
4. Give the relations of the radial artery, and name its branches.
5. Describe the spleen.
6. Name the points of surgical interest of the popliteal space.
7. Name the ligaments which suspend the uterus.
8. What area is drained by the right lymphatic duct?
9. Describe the elbow joints.
10. Describe the artificial divisions of the abdomen, and name the contents of each subdivision.
11. Describe the great sciatic nerve.
12. Describe the rectum.

PHYSIOLOGY.

1. Explain what is meant by "blood pressure" and "peripheral resistance."
2. At what point in the circulatory system does the blood flow most rapidly?
3. Which travels with greater rapidity, the pulse or the blood stream?
4. In what organ is lymph most rapidly formed?
5. How is digestion modified by the absence of hydrochloric acid from the gastric juice?
6. To what kind of diet is the addition of sodium chloride of most importance?
7. What are the limitations to the use of milk as the sole article of diet?
8. What is meant by "internal secretion"?
9. What is the chief source of urea?
10. What are the functions of the red blood corpuscles?
11. Why does the injection of a large quantity of normal saline solution into the vessels cause diuresis?
12. What are the functions of the pancreatic juice?

CHEMISTRY.

1. Define molecular weight.
2. Define potable, hard, and temporary hard water.
3. How is H_2S prepared? Write formula.
4. Describe the bismuth test for sugar in the urine. What is the objection to this test?
5. Mention chemical and physical properties of arsenic.
6. Upon what reaction does the copper test for sugar in the urine depend?
7. What do you understand by diffusion of gases?
8. What is the chemical antidote for bichloride of mercury?
9. What are the chemical incompatibilities of iron and antipyrine?
10. What are fats, what are soaps?
11. Give atomic weight and valence of hydrogen, lead, sulphur, and mercury.
12. What is the relation between albumin and the specific gravity, and sugar and the specific gravity of the urine?

HISTOLOGY.

1. To what part of the anatomy does histology apply?
2. What relation does a knowledge of histology bear to physiology?
3. Describe in a brief way the histology of the kidney.
4. Give the minute anatomy of the liver.
5. Name the minute endings of the bronchi.
6. What are Haversian canals and where found?
7. Mention the communication between the great systemic blood vessels.
8. Mention the three great groups into which the tissues of the body are divided.
9. What are the principal forms of fibrous tissue?
10. Mention principal difference between cartilage and bone.
11. What structures compose secreting glands?
12. What are lymphatic glands, and where are they found?

PATHOLOGY.

1. Describe in a brief way the pathology of yellow fever.
2. In what part of the system would you expect to find primarily the infectious element in yellow fever?
3. From results of recent investigations, what, in your opinion, is the infectious element in yellow fever, and how is it conveyed?
4. What other infectious disease, common in the country, the morbid appearances of which sometimes so much resemble those of yellow fever?
5. What, in your opinion, is the source of infection in malarial diseases?
6. In malarial cachexia, or chronic malarial poisoning, what morbid conditions are usually found?
7. A case—age 26. Recurring hematemesis, profuse—enormously enlarged spleen. Anemia—lemon-tinted skin—moderate general dropsy. Sclera bluish white; digestion poor, with inclination to costiveness. History: Two or three terms of chills in boyhood, each lasting one year or more. Diagnosis made without microscope. Gave him quinine in acid solution for six or eight weeks—nearly 400 grains in all. Spleen reduced like magic to almost normal size, no more hemorrhage, dropsy disappeared, skin resumed more natural tint, when he passed from under my care. What, in your opinion, was the morbidity causing the hemorrhage; and what caused this morbidity?
8. Where would you expect to find pathological lesions in hydrophobia, and mention some of the most pronounced.
9. What pathological lesions to be found in simple acute endocarditis?
10. How does endocarditis differ from acute plastic pericarditis pathologically?
11. Which of these will likely affect most seriously the circulation of the blood, and why?
12. Mention some disease which is most commonly the cause of either or both of these morbid conditions.

PRACTICE.

1. What is intestinal obstruction and its pathological anatomy?
2. In acute indigestion resulting in cholera morbus, what would be your first plan of treatment?
3. What are biliary calculi, their cause and treatment?
4. How would you diagnose and treat a case of gastric cancer?
5. What is sciatica, symptoms, and treatment?
6. What are the symptoms and treatment of acute catarrhal laryngitis?
7. How would you diagnose and treat a case of diphtheria?
8. What are the methods employed in making an examination of the heart? Describe the same in normal condition.
9. What is epilepsy, its cause, and varieties?
10. What is interstitial nephritis?
11. What is anemia, its causes, and pathological anatomy?
12. How would you diagnose a case of croupous pneumonia?

SURGERY.

1. Give the principal methods of abdominal drainage with which you are familiar. What method do you consider best?
2. How would you treat a case of ingrown toe-nail?
3. Mention the most important symptoms of an acute synovitis involving the hip-joint.
4. Give your treatment of a large varicose ulcer of the leg.
5. What are the principal signs of a simple fracture involving the femur?
6. What important tissues may be accidentally wounded during an operation for femoral hernia?
7. What are the symptoms of acute intestinal obstruction?

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

8. How should an aneurysm of the femoral artery be treated?
9. How would you treat a large varicocele?
10. Describe in detail how you would correct the deformity and dress a case of Colles' fracture.
11. Describe in detail how you would proceed to control hemorrhage during an amputation of the hip-joint.
12. How would you treat a carbuncle?

EYE, EAR, NOSE, AND THROAT.

(Four questions to be answered.)

1. What are the dangers of otitis media?
2. How would you make a differential diagnosis between a case of diphtheria and a bad case of follicular tonsillitis?
3. Upon what would you base a diagnosis of suppurating disease in the antrum of Highmore?
4. Describe in detail how you would proceed to remove a small foreign body embedded in the cornea.
5. Upon what symptoms would you make a diagnosis of mastoiditis?

OBSTETRICS.

1. (a) What is the connection between ovulation and menstruation? (b) What is the average duration of menstruation? (c) What is the interval between the menstrual periods? (d) Give the average age at which menstruation first occurs.
2. Describe the axis of the inlet and the outlet of the pelvis and the axis of the cavity.
3. How are the organs of generation divided, external and internal?
4. Describe the changes which occur in the ovum after impregnation.
5. (a) What are the uses of the liquor amnii during pregnancy? (b) During labor?
6. (a) What is puberty? (b) Describe the changes that take place in the female at puberty.
7. (a) What comprises the puerperal state? (b) Describe the maternal changes during that period.
8. Describe the lochia and the conditions that change its composition and quantity.
9. Give the diagnosis and treatment of trunk presentations.
10. In what way may delivery be arrested in twin births? Describe the management of the same.
11. Give the causes, diagnosis, and treatment of purulent ophthalmia neonatorum.
12. Give causes, pathology, and treatment of thrush.

HYGIENE.

1. What is the difference between a contagious and an infectious disease?
2. Describe two of the best methods of fumigation to prevent the spread of contagious diseases.
3. What steps are essential to prevent the spread of typhoid fever from a patient to other members of the household?
4. Describe a good plan for ventilating a sleeping-room in a temperate climate during winter.
5. What are the normal constituents of atmospheric air?
6. What are the deleterious ingredients of exhaled air?
7. What is meant by absolute and relative humidity?
8. What symptoms are produced in some persons by sudden changes from low to high altitudes?
9. Why should the principles of hygiene be observed in construction of dwellings?
10. In the selection of a building site, what things are to be sought and what avoided?
11. How would you guard against the bowel disturbances of infants during their first and second summers?
12. From what foods does ptomain poisoning arise?

MEDICAL JURISPRUDENCE.

1. Define forensic medicine.
2. Briefly enumerate the difference between an ordinary and a medical expert witness.
3. Enumerate the general rules to be observed in testifying as an expert witness.
4. Define criminal and civil malpractice.
5. Briefly enumerate what you would do if called to view the body of a person found dead.
6. What do you understand by personal identity?
7. Give a practical and reliable test for human blood.
8. State what is considered a live birth by law and what manifestations of life would establish it medico-legally.
9. If called to see a person before death suspected of having been poisoned, state what steps you would take to determine this fact both before and after death.
10. What do you understand by a dying declaration, and what is its value in court?
11. Give a differential diagnosis between opium poisoning, acute alcoholism, and apoplexy.
12. If called to view a person found dead from gunshot wound, state how you would determine as to whether it was probably suicide or murder.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS FOR THE STATE OF TEXAS, *October* 10, 17, *and* 18, 1906.

PHYSIOLOGY.

1. *Blood pressure* is the pressure on the blood due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance in the capillaries. This latter is called *peripheral resistance*.
2. At the beginning of the aorta.
3. The pulse travels at the rate of about fifteen to thirty feet per second in the arteries; the blood stream travels at the rate of about one foot per second in the arteries.
4. There are two theories as to the formation of lymph:—(1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence.
5. Proteid digestion may be slightly delayed.
6. Vegetable foods.
7. During the earliest months of life milk is a perfect food. Later on it will not suffice, as it contains too little iron; further, tremendous quantities of it would have to be ingested in order to ensure an adequate supply of carbon and nitrogen.
8. It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.
9. Urea is produced from the proteids of the food and tissues. It is chiefly formed in the liver.
10. To carry oxygen from the lungs to the tissues.
11. The normal salt solution abstracts water from the tissues of the body and causes a condition of hydremic plethora; the capillaries of the kidneys thus contain a greater quantity of blood, and capillary pressure is increased. The result is:—(1) more rapid filtration, and (2) an increased amount of urine.
12. (1) It changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; (2) it converts starch into maltose; (3) it emulsifies and saponifies fats; and (4) it causes milk to curdle.

CHEMISTRY.

1. Molecular weight is the weight of a molecule of a substance as compared with the weight of an atom of hydrogen. It may also be said to be the sum of the weights of the atoms composing its molecule.
2. A *potable* water is one that is apparently fit to drink. A *hard* water is one that forms a curdy deposit with soap. In a *temporary hard* water the hardness is due to the bicarbonates of magnesium and calcium, and can be removed by boiling and filtering.
3. H_2S may be prepared by treating ferrous sulphid with dilute sulphuric acid. Thus: $FeS + H_2SO_4 = FeSO_4 + H_2S$.
4. Albumin, if present, must be removed. Add to the urine enough Na_2CO_3 to render it strongly alkaline. Put about three cubic centimeters of the urine into a test tube, add a very small quantity of powdered bismuth subnitrate, and boil. If sugar is present the bismuth powder becomes black. The test is not reliable, for other substances than sugar will produce the reaction.
5. Arsenic is a brittle gray solid with a metallic lustre, or a black amorphous powder. It is insoluble in water, and is either odorless or has the odor of garlic. It is tarnished by moisture; in dry air it is not altered; heated in air it becomes arsenic trioxide. It combines with most metals, also with chlorine, bromine, iodine, sulphur, and with nascent hydrogen.
6. The boiling alkaline solution converts glucose into substances which are very easily oxidized, and are therefore good reducing agents. If cupric sulphate is present it is converted into cuprous sulphate, which latter is decomposed, and cuprous oxide is deposited.

7. When two gases are placed [illegible], or are separated from each other by a porous substance, the gases will pass into one another, and a homogeneous mixture is the result.

8. White of egg, in moderation, and followed by an emetic.

9. The chief incompatibles of *Iron* are: acids, acid salts, vegetable astringents, alkalies, and their carbonates. Of *Antipyrin*: nitrous compounds, ferric salts (in solution), nitrites (in solution), chloral hydrate, tincture of iodine, mercuric chloride, and tinctures containing iron or tannin.

10. *Fats* are mixtures of the glycerol esters of stearic, palmitic, and oleic acids. Soaps are the sodium or potassium salts of stearic, palmitic, and oleic acids.

11. Hydrogen: atomic weight, 1; valence, 1. Lead: atomic weight, 207; valence, 2 or 4. Sulphur: atomic weight, 32; valence, 2 or 6. Mercury: atomic weight, 200; valence, 2.

12. (1) The presence of *Albumin* may have no material effect upon the specific gravity of the urine, but (2) a specific gravity lower than normal has been held to denote the presence of albumin. *Sugar* in the urine causes a higher specific gravity.

HISTOLOGY.

1. Microscopically, to all parts.

2. *Histology* treats of the minute or microscopical structure of the various tissues and organs of the body; *physiology* is concerned with the functions of the same. Hence, a knowledge of the former is supposed to be an aid to the proper understanding of the latter.

5. The alveoli.

7. The capillaries.

8. Epiblastic, mesoblastic, and hypoblastic.

9. White fibrous, yellow elastic fibrous, mixed fibrous, mucous, and retiform; areolar and adipose tissues also contain some fibrous tissue.

10. Bone tissue is impregnated with lime salts.

11. A basement membrane, epithelial cells, vascular tissue with lymphatics, nerves, and capillaries, secreting cells which are capable of elaborating the elements proper to the particular secretion.

PATHOLOGY.

1. Rigor mortis is well marked, and appears early; the muscles are dark and dry; the skin is yellow or very dark, yellow green; subserous hemorrhages are found in the lungs and heart, and the blood may be thin and fluid. The gastric mucosa is strongly congested and swollen, and hemorrhages into the membrane and in the cavity are common; the blood is dark and thick; in the upper part of the small intestine similar lesions may be found, and in the colon there may be dysenteric necrosis. The liver is swollen, or moderately decreased, soft, and of a color varying from dark red to light yellow, with bile staining; the gall-bladder contains a small amount of dark, thick bile. The spleen [illegible] small. The kidneys show acute nephritis, often hemorrhagic. (Thayer's Pathology.)

2. In the blood.

3. Probably *Bacillus ictteroides* of Sanarelli. It is conveyed by the *Stegomyia fasciata* mosquito.

4. Severe bilious or remittent malarial fever.

5. The *plasmodium or hematozoon malariæ*, conveyed by the *anopheles* mosquito.

6. Secondary anemia; diminished number of white blood corpuscles; spleen enlarged, hard and pigmented; liver enlarged; kidneys pigmented; skin, dirty yellow color, and sometimes paraplegia and orchitis may be present.

7. Chronic malarial poisoning or malarial cachexia. Caused by the *plasmodium malariæ*.

8. The upper part of the spinal cord, pons, medulla, and cortex of the cerebrum. Hemorrhages, and dilated and congested blood-vessels.

9. Vegetations occur on the valves or in the lining membrane of the cavities of the heart. These vegetations consist, at first, of fibrin and leucocytes, later of connective tissue. Micro-organisms are also generally present.

11. The endocarditis; because the vegetations present may become broken off and carried by the circulation to distant parts of the body, thus causing embolism or infarction.

12. Both of these diseases may be caused by acute articular rheumatism.

PRACTICE.

2. Remove any irritant or offending matter; give calomel in fractional doses, and, to allay the pain, a hypodermic of morphine [illegible] and atropine (as in question 2 above), application of heat, and diffusible stimulants if shock is present. Prophylaxis includes: plain and easily digested food, the ingestion of plenty of good drinking water between meals, sufficient outdoor exercise, saline, and the avoidance of indigestion.

3. The predisposing causes are: age, sedentary habits, and obstruction of the bile ducts. The exciting cause is probably infection of the gall-bladder. The treatment during the [illegible] consists of chloroform, a hypodermic of morphine and atropine (as in question 2 above), application of heat, and diffusible stimulants if shock is present. Prophylaxis includes: plain and easily digested food, the ingestion of plenty of good drinking water between meals, sufficient outdoor exercise, saline, and the avoidance of indigestion.

7. For diagnosis, see below, *Eye, Ear, Nose, and Throat*, question 2.

SURGERY.

1. Gauze; rubber tubing; glass tubing; strands of gut, or horsehair, or silk. There is no one method that is universally best. For blood or serum, capillary drainage along a strip of gauze is best; for pus, the tubes are better employed.

3. Pain; limited movement of the joint; the limb is flexed, abducted, and everted; there may be tenderness and fullness in Scarpa's triangle and in the gluteal region; the muscles controlling the movements of the joint may undergo tonic contraction or become atrophied.

6. The obturator artery, if abnormal; the deep epigastric artery; the spermatic cord, in the male; the round ligament in the female. This latter is not of much consequence, but, if the spermatic cord is cut, the vas deferens and spermatic artery are also severed.

8. It may be treated by (1) extirpation, or (2) ligature of the common femoral or superficial femoral artery, or (3) by compression in the groin.

EYE, EAR, NOSE, AND THROAT.

1. Deafness or impairment of hearing; necrosis of the ossicles; caries or necrosis of the temporal bone; polypi; inflammation of the mastoid cells and antrum; cholesteatoma; facial paralysis; subcranial abscess; cerebral compression; meningitis; thrombosis of the lateral sinus; abscess in the cerebrum or cerebellum; death.

2. In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged, there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms and may be found on the fauces and pharynx as well as on the tonsils, in the exudate the Klebs-Löffler bacilli may be found.

In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Löffler bacilli are never found.

3. Pain; a periodic purulent discharge from the nose; the presence of pus on puncturing the antrum; and, sometimes, fracture. Transillumination will be of service.

4. "The eye is anæsthetized, the patient is seated facing a good light, with the surgeon standing behind and supporting the head; the lids are separated and the eyeball is steadied by the fingers of the left hand, the index finger is applied to the margin of the upper lid, and the middle finger to the lower lid, and the two fingers are separated, at the same time gently pressing backward. The instruments used are either the blunt spud, the gouge, or the foreign-body needle. When the foreign body is superficial, the blunt spud will answer. When it has penetrated into the corneal substance, it must be picked or dug out with the gouge, or the needle; in such cases, the instrument is passed behind the foreign body. The wound which results must be kept clean by frequent irrigation with solution of boric acid; frequently a protective bandage is indicated. If a ring of rust is present, this also should be removed. Care must be taken to inflict as little injury as possible, and when the foreign body is deep, not to perforate the cornea." (From May's "Diseases of the Eye.")

5. Intense pain, of a throbbing character in the ear or mastoid process; a depressed and tumefaction of the posterosuperior wall of the auditory canal; great tenderness on pressure over the mastoid region; swelling, redness, and edema of the mastoid process.

OBSTETRICS.

1. (a) The connection between ovulation and menstruation is not yet definitely settled, but the two functions seem to be closely associated. It has been held that ovulation is dependent upon menstruation; also that menstruation is dependent upon ovulation; it has also been proved that each may occur without the other, and it is possible that they are both dependent upon some common (and as yet unknown) cause.

(b) About three or four days.

(c) About twenty-eight days, from the beginning of one period to the beginning of the next.

(d) In this country, about fourteen years; in warmer climates it occurs earlier.

5. (a) (1) As a protection to the fetus against pressure

and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus.

(b) It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

HYGIENE.

1. An *infectious* disease is one that is caused by bacteria. A *contagious* disease is one that can be communicated to a healthy person by contact with one who is infected.

5. Oxygen, nitrogen, carbon dioxide, water vapor, argon, ammoniacal compounds, hydrocarbons, ozone, oxides of nitrogen, and solid particles.

6. Carbon dioxide, crowd poison, organic matter given off from the skin and lungs, fatty acids, and pathogenic bacteria.

7. *Absolute humidity* is the amount of watery vapor contained in the atmosphere, irrespective of the temperature. *Relative humidity* is the proportion of watery vapor in the atmosphere at a certain temperature, as compared with air completely saturated (which is expressed by 100).

8. Any of the following: giddiness, dyspnea, palpitation of the heart, headache, gasping for breath, dryness of the throat, intense thirst, general malaise, fatigue, loss of appetite, nausea, vomiting, tinnitus aurium, slight elevation of body temperature, and occasionally epistaxis, bleeding from the gums, bloodshot eyes, and hemoptysis.

MEDICAL JURISPRUDENCE.

1. Forensic Medicine has been defined as the application of medical, surgical, or obstetrical knowledge to the purposes of legal trials.

2. The ordinary witness testifies only to *facts*. An expert witness, in addition, gives his *opinion* on facts or supposed facts as noted by himself or asserted by others.

3. The following, which admirably answers this question, is from Witthaus and Becker's "Medical Jurisprudence":

(1) A physician should refuse to testify as an expert unless he is conscious that he is really qualified as an expert.

(2) After accepting the responsibility, his first duty should be to make a diligent examination and preparation for his testimony, unless it be upon a subject with which he is familiar, and which he is satisfied that he has already exhausted, by reading the best authorities that he can find, and by careful reflection upon particular questions as to which his opinion will be asked.

(3) Where he is to make an examination of facts, such as the post-mortem examination of a body, a chemcial analysis, or an examination of an alleged insane person, he should insist upon having plenty of time and full opportunity for doing his work thoroughly. He should take particular pains to make his examination open and fair, and, if possible, should invite opposing experts to cooperate with him in it.

(4) He should be honest with his client before the trial in advising him and giving him opinions, and upon the trial should observe an absolutely impartial attitude, concealing nothing, perverting nothing, exaggerating nothing.

(5) On the preliminary examination as to his qualifications as a witness, he should be frank and open in answering questions. He should state fully the extent and the limits of his personal experience and of his reading upon the subject, without shrinking from responsibility, yet without self-glorification.

(6) He should be simple, plain, and clear in his statement of scientific facts and principles, avoiding the use of technical language, and trying to put his ideas in such form that they will be grasped and comprehended by men of ordinary education and intelligence.

(7) He should avoid stating any conclusions or principles of which he is not certain, but having an assurance that he is right he should be firm and positive. He should admit the limitations of his knowledge and ability. Where a question is asked that he cannot answer, he should not hesitate to say so, but he should refuse to be led outside the subject of inquiry, and should confine his testimony to those scientific questions which are really involved in the case, or in his examination of the case.

(8) He should always bear in mind that at the close of his testimony an opportunity is usually given to him to explain anything which he may be conscious of having said which requires explanation, and partial statements which need a qualification to make them a truth. This is the physician's opportunity to set himself right with the court and with the jury. If the course of the examination has been unsatisfactory to him, he can then, by a brief and plain statement of the general points which he has intended to convey by his testimony, sweep away all the confusion and uncertainty arising from the long examination and cross-examination, and can often succeed in producing for the first time the impression which he desires to produce, and can present the scientific aspects of the case briefly and correctly.

8. To constitute a "live birth," there must be (1) complete extrusion of the child from its mother's body, and (2) some certain sign of life. The latter would be established by one or more of the following: pulsation of the cord, beating of the child's heart, motions of the limbs, twitchings of the muscles, wrinkling of the brows, puckering of the face, opening of the eyes, even if respiration does not take place. (From Witthaus and Becker's "Medical Jurisprudence, etc.")

10. By a "dying declaration" is understood any statement made by a dying person who believes that he cannot recover, and that he is, at that very time, in actual danger of death. The statement need not be sworn to; it should be voluntary and sincere, and it is admissible as evidence in a court if the individual making it dies.

BULLETIN OF APPROACHING EXAMINATIONS †

STATE	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery.	Montgomery.	March 1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	April 1
Arkansas*	F. T. Murphy, Brinkley	Little Rock.	April 9
California	Chas. L. Tisdale, Alameda	San Francisco	April 10
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver.	April 2
Connecticut*	Chas. A. Tuttle New Haven	New Haven.	March 1.
Delaware	J. H. Wilson, Dover	Dover.	June 12
Dis. of Col'bia	W. C. Woodward, Washington	Washington	April 11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May 15
Georgia	E. R. Anthony, Griffin	Atlanta.	April —
Idaho	J. L. Conant, Jr., Genesee	Boise.	April 2
Illinois	J. A. Egan, Springfield	Chicago	April 17
Indiana	W. T. Gott, 129 State House, Indianapolis	Indianapolis.	May 28
Iowa	J. F. Kennedy, Des Moines	Des Moines	March '10
Kansas	T. F. Raines, Concordia	Topeka	Feb. 12
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April
Louisiana	F. A. La Rue, 211 Camp St., New Orleans	New Orleans	May 9
Maine	Wm. J. Mayburv, Saco.	Portland	March 5
Maryland	J. McP. Scott, Hagerstown	Baltimore	June —
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 1
Michigan	B. D. Hanson, 295 Whitney Building, Detroit	Ann Arbor	June 11
Minnesota	O. E. Lanier, 24 South Fourth Street, Minneapolis	St. Paul	April 2
Mississippi	J. F. Hunter, Jackson	Jackson	May 14
Missouri	J. A. B. Adcock, Warrensburg	St. Louis / Kansas City	April 17
Montana*	Wm. C. Riddell, Helena	Helena.	April
Nebraska	Geo. H. Brash, Beatrice	Lincoln	Feb 1
Nevada	S. L. Lee, Carson City	Carson City	Feb 1
N. Hamp're*	Henry C. Morrison, State Library, Concord	Concord	
New Jersey	J. W. Bennett, Long Branch	Trenton	June 18
New Mexico	B. D. Black, Las Vegas	Santa Fe.	June
New York	C. F. Wheelock Univ. of State of New York, Albany	New York, Albany, Syracuse Buffalo	May 21
N. Carolina*	G. T. Sykes, Grissom	Morehead City	May —
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April 2
Ohio	Geo. H. Matson, Columbus	Columbus	June 11
Oklahoma*	J. W. Baker, Enid	Guthrie	March 26
Oregon*	B. E. Miller, Portland	Portland	April —
Pennsylvania	N. C. Schaeffer, Harrisburg.	Philadelphia / Pittsburg.	June —
Rhode Island	G. T. Swarts, Providence	Providence	April 4
S. Carolina	W. M. Lester, Columbia	Columbia	June —
S. Dakota	H. E. McNutt, Aberdeen.	Sioux Falls	July
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville	May
Texas	T. T. Jackson, San Antonio	Austin	April
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	April
Vermont	W. Scott Nay, Underhill	Burlington	July
Virginia	R. S. Martin, Stuart	Lynchburg	June
Washington*	C. W. Sharples, Seattle	Spokane	July
W. Virginia*	H. A. Barbee, Point Pleasant	Wheeling	April
Wisconsin	J. V. Stevens, Jefferson	Madison	July
Wyoming	S. B. Miller, Laramie	Cheyenne	

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for details regarding the examination in any particular State.

Illinois and Indiana.—The reciprocity in medical licensure which has existed between these two States is no longer in force. This is not the first time that disagreement on this subject has occurred between Illinois and Indiana. Reciprocity was originally established between these States in 1902; in January, 1904, the Illinois State board broke off reciprocal relations with Indiana. Reciprocity was reestablished on January 1, 1905, but lasted only until July, 1906, when Indiana returned the compliment and broke off reciprocal relations. Illinois was notified of this in November, 1906.

New Instruments.

A STERILE EYE BATH.

By C. EVERETT FIELD, M.D.,

RICHMOND HILL, L. I.

In ophthalmic practice we sometimes neglect to make full use of the common eye bath for irrigation purposes. Objections have been raised many times against both glass and hard rubber devices; still they have done good service.

An eye bath fashioned from a single piece of aluminum has been made for me by the Kress & Owen Company. That this little device will be well received by the medical profession is not to be questioned when one considers the many points of advantage this metal cup has over the old style glass contrivance. It is cleanly, unbreakable, and can be sterilized instantly by dropping into boiling water.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 26, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	420	197
Diphtheria	273	34
Measles	181	6
Scarlet Fever	268	7
Smallpox	2	—
Varicella	263	—
Typhoid Fever	35	9
Whooping Cough	54	5
Cerebrospinal Meningitis	14	14
Malarial Fever	..	..
Totals	1410	272

A Case of Pick's Disease.—E. Tranquilli describes a case of peridiaphragmitis, or Pick's disease. This is a morbid entity of complex nature, not a pure and simple peritonitis. It may result from tuberculosis or from syphilitic inflammation with sclerosis. The central tendon of the diaphragm is the structure that has to do with the absorption of corpuscular substances. The disease begins as an inflammation of the diaphragm, which ends in sclerosis of the central tendon and pressure on the inferior vena cava. In the author's case there was marked ascites, the fluid being confined to the abdomen, with no edema of the limbs. The quantity of fluid was sufficient to require frequent tapping. The patient had mediastinal pericarditis, left exudative pleurisy, chronic peritonitis with exudate in the abdomen, and perihepatitis, due to stasis of peripheral origin. In this disease the kidneys are not diseased and the urine is normal, although often increased in amount. The heart is usually normal, and hence the long resistance to the disease which is essentially chronic, and may run on for fifteen or more years. The sclerosis begins in the diaphragm and is propagated toward the pericardium and pleura. Treatment requires paracentesis to relieve the pressure of the fluid. Aside from this tubercular remedies when it is of tubercular nature, and iodide of potassium and arsenic when regarded as of syphilitic origin.—*Gazetta Medica di Roma.*

Obstruction of the Ileocecal Orifice and Appendicitis Proper: Treatment.—W. C. Abbott calls attention to the confusion sometimes existing in the diagnosis of appendicitis proper. He cites several cases in point. Although the typical case of true appendicitis is not difficult to diagnose, it is not always possible definitely to differentiate mild cases of appendicular inflammation from other conditions having similar symptoms. Tenderness upon pressure about McBurney's point or in the right iliac fossa, with nausea and diarrhea, or obstinate constipation, with rapid pulse and a rise of temperature, may all be caused by disorders outside of the appendix entirely. The writer believes that in certain cases inflammatory conditions exist about the ileocecal orifice that are diagnosed and operated upon for appendicitis, which would, if the bowels were freely opened and spasm and congestion relieved, recover within a short time.—*The American Journal of Clinical Medicine.*

Bier Treatment in Acute Purulent Otitis and Mastoiditis.—Basing his experience on seven cases of acute otitis media purulenta with acute mastoiditis and one case of distinct subperiostea abscess, S. J. Kopetsky offers the following conclusions as to the value of artificially induced hyperemia (Bier method) in this class of cases: (1) If used early it will greatly increase the probabilities of curing the condition without resort to major operative measures. (2) In cases cured under its influence the reestablishment of ear function will occur quicker than under the usual line of treatment. (3) Its use by the inexperienced is absolutely dangerous. (4) Its employment should be limited to the young and the otherwise healthy. (5) Finally we submit that when the indications are kept in mind and when properly and intelligently used, induced hyperemia will be found a measure destined, when its scope and limitations are better understood, to find a permanent place in otological therapeutics.—*Archives of Otology.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 25, 1907:

FRESH AIR TREATMENT IN HOSPITAL WARDS.*

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE PRESBYTERIAN AND BELLEVUE HOSPITALS.

THE general medical hospital ward as exemplified in most of the hospitals in this city is a most uncomfortable and irrational place for the proper care of the sick. In the same long, narrow room are crowded a miscellaneous collection of ailments, all submitted to identical conditions and surroundings, without the slightest attempt at appropriate adaptation of environment. The pneumonia patient, with a temperature of 105° F., sorely in need of fresh, cool air, lies in the next bed to the uremic patient with a subnormal temperature and high tension pulse, who needs warm air and a hot pack! The typhoid fever patient, with a racking headache and photophobia, lies facing a glare of sunlight, which is doubtless beneficial to the man with pernicious anemia in the next bed (because the trained nurses think the ward looks better with the shades all at the same height). The neurasthenic with insomnia lies next to the patient with alcoholic cirrhosis and delirium tremens, who keeps the entire ward awake most of the night. The convalescent patient has nowhere to go during the day for a change of air and scene, and the poor old woman with a little chronic cough, who needs to rest in an easy chair toasting her feet at a heater, sits gazing wistfully and pathetically at a hole in the wall near the ceiling, where some architect (who never built a hospital before) has seen fit to place a hot-air register. But these are minor inconsistencies. The greatest evil of all is that the ward is "ventilated" by a thermometer, a little instrument which from October to May is kept steadily at 68° or 70° day and night, without regard to the moisture of the air, its freshness, its CO_2 content, its nitrogenous waste, its pollution with fetid odors, emanations from foul stools, foul breaths, and foul perspirations. Without regard also to the fact that during the visiting hours, or during the admission of classes of students or probationer nurses, the ward air, which ought to belong primarily to the patients, has been breathed for them by double and sometimes treble their number of outsiders. In some very much "up-to-date" institutions, the thermometer is replaced by an electric thermostat, communicating its valuable data to the superintendent's office, so that he may rest assured that in the wards above the air is always at 70° F., no matter if it is 15 per cent. CO_2 or hydrogen sulphide, for all he knows. The functionary usually placed in charge of this ingenious system is the hospital engineer, who is about as much of a ventilation expert as a hibernating dormouse. The nurses (who are given elaborate lectures on hygiene, and "how to ventilate the sick-room") are not allowed to raise a window as much as a crack from October to May, and as for the house staff—why, of course it is not for mere doctors to stoop to such details! One of our representative hospitals in which that most pernicious of all ventilating systems, known as the "closed system," was placed some eighteen years ago, with the endorsement of the Medical Board and at extraordinary cost, originally had locks and keys attached to its windows, and in lavatories the windows were, in addition, screwed down with bolts! Would anyone of us consent to live from October to May in a house in which his bedroom windows were locked fast and his lavatory window screwed to the sill? But we are in and out, getting the stimulus of a *change* of air, a change of temperature, as well as of air composition. The bedridden patient, on the other hand, lies perpetually at the mercy of the superheated air which is supplied him. The fundamental fault of the "closed ventilation" system is that heating and ventilation are made inseparable, and to deliver through long conduits air hot enough to warm a large number of distinct wards, it must be first superheated to about 400° F. and then all doors and windows must be kept tightly closed, for the opening of a single window in one ward "short-circuits" the entire system, and temporarily cuts out all the wards from both heat and air supply. This system may work in large assembly halls, such as churches or theaters, but there it is not continuous, and the people come and go, and refresh themselves with normal outdoor air. Superheated air is like superheated or sterilized milk—one can live upon it, of course, but there is nothing "uplifting" about it (as Walter James has said, in writing on this topic), and it admits of no advancement in health. I am convinced that there are properties which, for lack of better term, we call "vital" in the outdoor air that are not measurable by any of our present instruments of precision, such as the thermometer, hygrometer, thermostat, barometer, etc. It is only a few years since it was supposed that all was known about the chemical composition of atmospheric air. Then argon and other new elements were discovered. It is not unreasonable to believe also that some of the physical properties of the air are more or less permanently altered by its confinement and superheating.

Being unable to find any recorded scientific data upon the quality of hospital ward air, I undertook to obtain some a year ago in the wards of the Presbyterian Hospital. A study of the CO_2 content of the wards was made under varying conditions. The analyses were performed for me by Dr. C. G. L. Wolf (Instructor in Chemistry and Physics in the Cornell University Medical College in New York City), and the results were very illuminating. The experiments were carefully made, unusually

*A paper read before the New York Academy of Medicine, January 17, 1907.

large quantities of air were used to lessen liability to error, and control tests were made upon the hospital roof air and that of Dr. Wolf's laboratory, in which the chemical analyses were conducted. Without going into details, I will quote briefly from the conclusions of our report, which was submitted to the managers of the hospital: (1) Pure, normal atmospheric fresh air is admitted to contain 4 volumes of CO_2 per 10,000 volumes of air; 4.5 parts CO_2 represent highly impure air, 5 parts injurious air, and 6 to 7 parts air wholly unfit to breathe. (2) When the fresh air on the roof was practically normal (4.06 parts CO_2) that in the wards, with the most complete closed ventilation system in full operation, contained as much as 4.71 parts CO_2, and after twenty visitors and four nurses had spent one hour in the word this content rose to 5.13 parts. Immediately thereafter the ward windows were opened for ten minutes only, and the CO_2 content fell to 4.34 parts, although on a cold December day the ward temperature was lowered thereby only 3° F. Hence, with almost imperceptible change, as shown by the pernicious thermometer, the air impurities, which had been increased more than 20 per cent. by the visitors, were nearly eradicated by ten minutes of *window opening*. (Truly the nose is mightier than the thermometer as a ventilation guide!) (3) Of course the CO_2 content is only one of the many forms of atmospheric vitiation, but it is known to rise and fall *pari passu* with other impurities, and is therefore a fair index of the other conditions of vitiation. (4) In connection with these experiments others were made by Dr. G. A. Tuttle in the bacteriological laboratory of the hospital to demonstrate the injurious effect of raising dust by dry sweeping, so common in American hospitals. On an exposed agar plate 26 colonies of bacteria were deposited in quiet ward air. When the air was agitated by dry sweeping the number rose to 532 colonies, or more than twenty times as many colonies of streptococci, staphylococci, diplococci, with spores, fungi, and a variety of miscellaneous organisms. This was in a ward thoroughly cleaned every day.

Several years ago, while simultaneously visiting in two hospitals, I observed a very striking difference in certain classes of patients, especially those with marked anemias, chronic sepsis, pulmonary and chronic cardiac diseases, etc. In one the patients were supplied solely with superheated air forced through thousands of feet of metal conduits, and during their entire stay in hospital never received one single breath of unbaked air. Some of them improved, others grew well, to be sure, but they were a very long time about it. The other hospital is one of our oldest. The windows have settled, gusts of air and even the snows blow in through wide cracks. The wards are heated by steam pipes, and when too hot or too close the windows are opened, and even in midwinter are sometimes left open all day. Each patient receives good daily allowance of pure, fresh, unroasted air. The difference was really very striking in the greater promptness of recovery in favor of the old, tumbledown hospital that used to be an almshouse ninety odd years ago. It was so striking that we sought to do better, and as the old almshouse is the only hospital in this entire city that has adequate balcony accommodations attached to the wards we began to move the patients' beds out on the verandas. First the tuberculous were moved out, later the pneumonias, and later still any case that could be distinctly benefited by air which had never been in anyone else's lungs. At the Presbyterian Hospital we have as yet no balconies; but we have small rooms opening off the wards. In these we have sealed up the artificial ventilation system so that the windows may be kept open day and night, and a patient at the corner of Madison avenue and Seventy-first street who is dying for lack of fresh air, can get it without freezing out a surgical patient on the corner of Park avenue and Seventy-first street by short-circuiting his air supply! In these small rooms, as far as their capacity admits, we now place all those needing uncooked air, and the effect in certain cases is truly magical. We have made further improvement in the wards themselves by requiring that the windows be simultaneously opened widely at least twice a day to thoroughly air the ward, like any other bedroom, and by requiring that the night temperature be kept five degrees lower than that of the day, for there is something stimulating to respiration in such change which is lacking at the monotonous 70° F. level.

The most striking benefit of the uncooked air treatment is shown in cases of pneumonia. Delirious alcoholic patients, with profound cyanosis, when taken out of the general ward and placed at windows open day and night, become much less nervous and restless, and distinctly less cyanosed. I formerly gave such patients oxygen sedatives, whiskey, and other stimulants. In the open air they, of course, receive no oxygen, and require far less of stimulants and sedatives. During 1906 we treated in all at the Presbyterian Hospital 128 cases of acute lobar pneumonia. Of these patients 47, or 36.7 per cent., received absolutely no drugs whatever—no stimulants, no narcotics, no inhalations, no "specifics," nothing except the occasional laxative, which anyone in bed with fever may require, and they all recovered, in the usual way, when the time came. Some defervesced by crisis, some by lysis, some in five days, some in 12 days, or other intervals. A large proportion of these patients received the uncooked air treatment and enjoyed it. The air temperature was often as low as 35° F. or 40° F. They never complained, except when some emergency required them to be taken back to the ward, as when the room was needed for some other patient in more urgent condition. They were not all thus treated merely from lack of sufficient isolation rooms or balconies. The remaining ward patients who recovered received various drugs or stimulants, solely because certain complications arose which needed treatment. But I would again emphasize the fact that of 128 patients with pneumonia, 36.7 per cent. made complete recovery in the usual time, without any medication, and for the most part with their heads lying close to open windows in midwinter weather.

Other diseases that do remarkably well with open window treatment are cerebrospinal meningitis, chronic sepsis, and all forms of anemia. The meningitis patients become very much quieter, sleep much better, and look better in every way. A patient with a pernicious anemia in which the red blood corpuscles numbered only 828,000 gained over a million red cells in a week when I took her out of the general ward and placed her in a small room with wide open windows. She left the hospital a few weeks later, with over 4,000,000 red cells, and a hemoglobin estimation that had risen from 20 to 80 per cent.

When the pneumonia or other febrile cases require a cold bath, or the use of a bedpan, or any procedure necessitating exposure, they are temporarily taken into the ward, or the windows of their rooms are closed, and the rooms warmed.

All this is nothing new, but it is well sometimes to preach again from old and well established texts. Forty-two years ago there was an epidemic of typhus and typhoid fever in New York City. As the wards of Bellevue Hospital became overcrowded, 520 patients were transferred to Blackwell's Island and placed outdoors under tents, in the late autumn and early winter. Dr. Austin Flint in his Practice of Medicine (5th ed., p. 978), in writing of this incident stated: "The average death-rate in the hospital wards was 1 in 5.97; in the tents 1 in 16.77." "Making the fullest allowance for the conjecture that the cases in the tents were milder than those in the hospital wards, it can hardly be doubted that the superior ventilation in the tents was the means of saving many lives." Fifty-six years ago Dr. John H. Griscom reported in this Academy the treatment by open air in Perth Amboy, New Jersey, of 82 cases of typhus fever. The patients who were derived from an immigrant ship, had the additional advantage of being soaked by a thunder shower, and all made good recovery from the fever. (Flint, *loc. cit.*) Eighteen years ago, during a reconstruction of the Presbyterian Hospital after the fire, I treated a number of cases of erysipelas, with high fever, in open tents on the hospital grounds, with excellent results. Every midwinter army campaign in which the sick and wounded have had tent treatment has shown anew the advantages of outdoor air. In answer to those who object to giving a pneumonia patient first-hand, unbreathed uncooked air (and such objectors have usually never seen the treatment tried), it should be stated that this form of treatment is not a temporary fad or a "fresh-air crusade," but a very old, well tried, and widely tried, common-sense method, from which we have been somewhat led away of recent years. The undesirable necessity of building large metropolitan hospitals of the "sky-scraper" type, the idea of massing all manner of heterogeneous cases with a series of long wards, all precisely the same, like sheep corrals, and the inhumanity of architects, who strangely prefer mansard roofs and straight ornamental façades to roof gardens and ward balconies, pernicious application of wholesale ventilation "systems" for the air supply of the air-hungered —these are some of the factors which have led us to turn from the open window and fix our exalted gaze upon the cast iron heater in the wall!

In Continental Europe they are far ahead of us in modern hospital construction in many different countries. Closed ventilation systems are practically unknown. Windows are built with transoms of different sizes, permitting easy regulation of the ward air. Heaters, porcelain stoves, and even open fires, are placed where patients who feel cold and need warmth may sit and be comforted. Numerous small rooms of variable sizes admit of the scientific classification of patients, especially as regards their individual requirements for ventilation and air temperature (two essentially different things). Attractive day rooms are provided next the wards, so that convalescents not only obtain change of air, scene, and occupation, but leave fresher air in the wards for the benefit of the very ill. Many visitors are thus kept out of the wards by being admitted to the day rooms instead. The evil of dry sweeping in the wards is unheard of. Finally, broad, open corridors abound, and attractive grounds, with shelter tents, are so arranged that patients have free access to them at all times. In all these things we have very much to learn, especially just now, while propositions are already before us to spend $29,000,000 (see MEDICAL RECORD, January 5, 1907, Stephen Smith on "A Hospital System for New York") of the taxpayers' money for new public hospitals.

I have purposely thus far omitted mention of tuberculosis, because the object of this meeting is to stimulate interest in the application of fresh air—not necessarily cold air, but always *fresh* air—treatment to a very large variety of other diseases. Tuberculosis has demonstrated for us that fresh air acts not as a specific for any one disease, but by increasing the resisting power of the organism against many diseases. To this end we should learn to adapt our modern hospital construction as well as that of our own homes.

The following conclusions for the betterment of ward ventilation in this cold and very changeable climate are submitted:

1. Ward heating and ward ventilation should be capable of independent adjustment at all times.

2. The night temperature of the ward should be at least 5° F. below the noon day temperature, which latter should not be above 68° F. or 70° F.

3. The ward windows should be furnished with transoms and one or two movable separate panes, to admit of easy regulation and ventilation.

4. No window should be so heavy that it cannot be readily handled by the nurse.

5. The ward should be in communication with balconies or porches, on to which patients' beds can be moved through windows of the casement type. Such balconies need not interfere with the adequate lighting and ventilating of the ward, as proved at the Bellevue and other hospitals in which they have been used. (They are being put upon all the wards of the new Bellevue).

6. The building of very large wards should be discouraged and a greater number of small adjacent rooms should be provided to admit of the scientific adjustment of the ventilation and temperature to suit the requirements of different patients.

7. The windows of the ward, even on the coldest day, should be opened at least twice daily, in the early morning and late afternoon, for a few minutes to thoroughly change all the air in the room. During this time any patient may be covered temporarily with extra bed clothing if there be fear of exposure from draft. The same procedure should be carried out immediately after visiting hours.

8. Day rooms should be provided for convalescents where they can obtain change of air and scene, and leave more fresh air for the bedridden patients in the wards.

9. The ward should have at least one *accessible* heater, where patients temporarily sitting up may gather and warm their feet if desirable.

10. It is entirely unnecessary to have all the ward windows precisely alike, except from some fanciful esthetic standpoint. Thus certain windows of the casement type should spring from the floor and give on to balconies. Obviously heaters cannot stand in front of these windows as they should in front of other shorter windows of the ordinary height. Windows should be grouped with more reference to sunlight exposure, ordinary wind exposure, etc., than is usually done.

11. House staff and nurses should not only be taught ventilation theoretically, but made to put it into practice in the wards, and should be made to regard fresh air as of equal importance with fresh food.

Where these simple common-sense principles are in daily practice it is possible to use fresh air as a definite therapeutic means and secure most gratifying results. Finally, air temperature and ventilation are *not* synonymous terms!

RESECTION OF THE SIGMOID FLEXURE.

By JOHN J. McGRATH, M.D.,

NEW YORK.

PROFESSOR OF OPERATIVE SURGERY AT THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL; VISITING SURGEON TO THE HARLEM AND COLUMBUS HOSPITALS; CONSULTING SURGEON TO THE NEW YORK FOUNDLING AND BRATTLEBORO MEMORIAL HOSPITALS.

THIS case is reported primarily for the purpose of calling attention to a simple method of end-to-end intestinal anastomosis which has been practised by the writer upon numerous occasions during the past two or three years.

Joseph J., aged sixty-three, native of the West Indies, was admitted to the service of Dr. J. T. Joseph Bird in the Harlem Hospital, November 20, 1906,

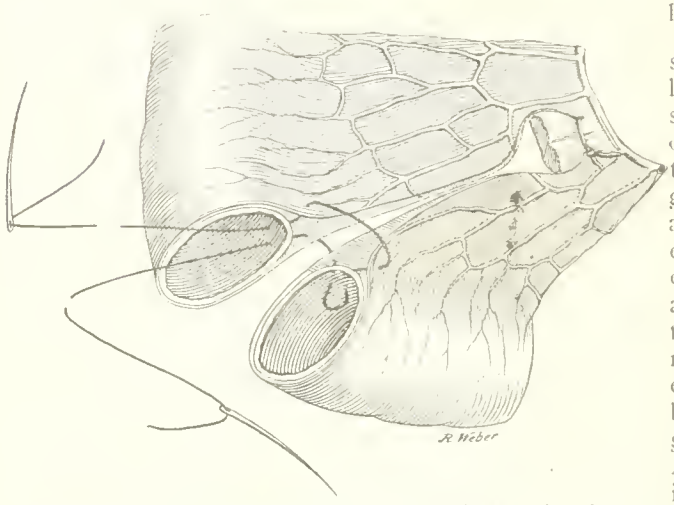

FIG. 1.—The mesenteric suture has been introduced; when drawn tight and tied it obliterates the "dead space" seen between the diverging layers of the mesentery; it also opposes the serous layers.

suffering from acute intestinal obstruction. The diagnosis of volvulus was made and operation advised.

Operation November 21. Chloroform anesthesia. An incision made in the middle line exposed the greatly distended gangrenous sigmoid flexure, which was twisted upon its mesentery through four complete turns. The twisted portion of the bowel corresponding to the entire sigmoid flexure was resected. An end-to-end anastomosis was made between the end of the descending colon and the end of the rectum by the method which is described in detail below.

After the lapse of three weeks the patient was discharged cured.

Description of the Method.—Two straight needles are threaded upon a piece of silk thread about twenty-four inches long, and with this as a suture the two ends of the bowel are joined together at their mesenteric border. In order to facilitate the description of the application of this mesenteric suture, we shall speak of the two ends of the bowel that are to be joined as the first and second ends. The suture is passed through the edge of the first end of the bowel entering upon the mucous surface near the mesenteric border; it passes across the mesenteric "dead space" and pierces the mesenteric serous layer; it then passes through the edge of the second end of the bowel, piercing its mesenteric serous layer, and after traversing the "dead space" emerges upon its mucous surface. The suture is then passed back in reverse order through the edge of the second end of the bowel entering upon the mucous surface alongside of the point where it had just emerged, and after traversing the "dead space" it pierces the mesenteric serous layer of this second end of the bowel; finally the suture is carried through the edge of the first end of the bowel, piercing the mesenteric serous layer, passing across the "dead space," and emerging upon the mucous surface of the bowel alongside of the point where it was first entered. The ends of the suture still carrying the two needles are left long for the purpose of continuing and completing the union of the two ends of the bowel. When the mesenteric suture is drawn tight it brings the two ends of the gut together, obliterating the "dead space" absolutely and bringing the corresponding mesenteric serous surfaces into accurate apposition. When the suture is tied it retains the parts thus closely applied permanently. The proper application of the mesenteric suture is the most important and essential step of the entire procedure.

The edges of the two ends of the gut are now secured with a silk tractor suture at a point nearly half way around their circumference—nearly opposite the mesenteric border. Making traction with one tail of the mesenteric suture and the silk tractor, the edges of the two ends of the bowel are sewed together with the other tail of the mesenteric suture as far along as the silk tractor, thus joining the two ends of the bowel for nearly half their circumference. The tractor being of no further use is cut and removed. A second silk tractor is applied so as to secure those edges of the bowel which still remain unsutured at a point about one-third of the circumference of the gut distant from the mesenteric border, and these edges of the bowel are sewed together with the second tail of the mesenteric suture. After this portion of the suture has been introduced, it will be seen that the edges of the bowel have been united for more than two-thirds of their circumference. The second tractor is of no further use and is cut away.

The gut is now spread out lengthwise, and it will be seen that there remains an opening to be closed corresponding to less than one-third of the circumference of the bowel, and this final step of the operation is accomplished with a nonpenetrating Lembert stitch, using the remaining portions of the two tails of the original mesenteric suture which still carry

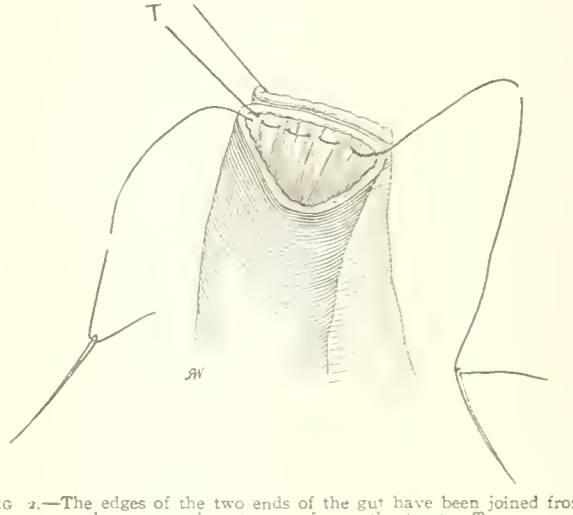

FIG. 2.—The edges of the two ends of the gut have been joined from the mesenteric suture as far as the tractor T.

the two needles for this purpose. Each of the two needles, which had last emerged upon the mucous surface of the gut, is thrust through the edge of the gut, so that it emerges upon the serous surfaces, and with these the opening that remains (corresponding to less than one-third of the circumference) is closed. A Lembert stitch is used for this purpose, with each thrust of the needle taking

a good secure bite in the serous and muscular coats, but not penetrating the mucous membrane layer. Finally the operation is completed by tying the two ends of the suture together.

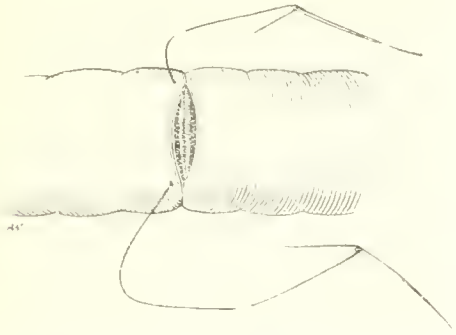

Fig. 3.—The gut has been joined for more than two-thirds of its circumference, and the sutures have been brought out through the edges of the gut for the purpose of completing the anastomosis with the Lembert stitch.

When the suture is applied at the mesenteric border and tied the mesenteric "dead space" is obliterated and the serous mesenteric layers are brought right down into close contact with the wall of the gut—two conditions that are absolutely essential to a successful end-to-end intestinal anastomosis. The ends of this same mesenteric suture are used to accomplish the union of the two ends of gut, using the tractors to facilitate the application of the suture as far as possible and finally completing the union with the Lembert stitch. For that portion of the anastomosis which is made with the assistance of the tractors a through-and-through stitch is used. The suture line should be placed at least one-quarter-inch below the edges of the gut, and the individual needle thrusts should be made about one eighth-inch apart. Each stitch is drawn fairly tight, and at every fifth or sixth thrust a back-stitch is made so as to prevent "pursing" of the suture.

The advantages of this method of anastomosis are its simplicity and efficiency and the fact that no apparatus, button, clamp, or other mechanism is necessary to its accomplishment.

CONSERVATIVE SURGERY IN SEVERE INFLAMMATORY AFFECTIONS OF THE UTERINE ADNEXA.*

By HIRAM N. VINEBERG, M.D.,

NEW YORK.

It was with readiness that I accepted the kind invitation of your chairman to participate in the discussion of the subject that is placed before you to-night.

From the outset of my active career in gynecological surgery I was deeply interested in the subject of conservative surgery in pelvic diseases. At that time it was not so much in vogue as it is now. Then it was customary if both tubes were markedly diseased to take little heed of the ovaries and to make a clean sweep of the pelvic organs. It was then held that in the face of so much inflammatory disease of the tubes the ovaries were disorganized or secondarily involved through adhesions, and that it did not pay to try to save them. There are a good many prominent gynecologists at the present day who still hold that view. But all are beginning to have more respect for ovarian tissue, so as to maintain the function of menstruation if the patient is under forty years of age. Whether or not we accept the theory that the ovary has the capacity of providing an internal secretion, we all admit that it is of considerable moment to the woman's economy to preserve her menstrual function if she be still several years on this side of the average age of the normal climacteric. All have ceased some time since to remove so-called microcystic ovaries for various nervous disorders and for vague pelvic symptoms. But in the subject before us a serious question arises. Is it wise, or even justifiable, in the presence of extensive inflammatory affections of the pelvic organs to retain a part of or an entire ovary that has been bound down by adhesions and is in a ragged and more or less pathological condition? This question will be answered variously by different operators. Some who have had unfortunate experiences and have had to do a second laparotomy a short time after the first to remove the ovarian structures that they left behind at the first, will be strong in their condemnation of what they term "false conservative surgery." Others, again, who have been chagrined and disappointed with their results in their efforts to do conservative surgery, will be equally strong in their condemnation. They will tell you the patient was not benefited thereby, that she continued having the same symptoms as before the operation, although on bimanual examination no marked changes could be found. To the latter I would say that they operated upon wrong indications. To my mind one of the most common causes of disappointment in conservative surgery upon the adnexa is the negligence of taking into account the condition of the uterus itself.

Let me cite a case. A young, healthy woman goes through a normal gestation, has a normal labor, and apparently a normal puerperium. Six months or a year later she begins to suffer from pelvic uneasiness, has a feeling of weight in the hypogastrium, a soreness or a burning in one or other groin or in both, has more or less backache. She is examined by a prominent gynecologist who may also be the obstetrician who delivered her. He finds everything apparently normal. There may be some tenderness over one or other adnexa on pressure. He puts the case down as one of neurasthenia. The symptoms, nevertheless, persist and she goes from one specialist to another. Later on she may have an attack laying her up in bed, attended with moderate elevation of temperature. The pelvic examination still does not show any marked changes. The patient grows tired of being treated locally without any relief, and clamors for an operation if it holds out any promise of cure. The abdomen is opened, the adnexa themselves are found fairly normal, there are evidences of more or less perisalpingitis resulting in membranous adhesions. These are broken up, and one or more cysts of varying size from a kidney bean to an almond in either ovary are found and excised. The patient makes an afebrile recovery. But she is no better afterward. In fact, her symptoms persist and grow steadily worse. In the course of a year or longer the abdomen is opened again, this time for the purpose of doing a radical operation. The portion of the adnexa left at the former operation seems to have undergone but little change. More adhesions are probably met with, some, no doubt, as a result of the prior interference, and the uterus now is so large as to arrest attention. The patient is cured after the second operation, although she may suffer very markedly from the nervous disturbance attending the artificial climacteric. This is not a fanciful case, but is the exact portrayal of an actual one, and is

*Read at a meeting of the Section on Obstetrics and Gynecology of the New York Academy of Medicine, December 27, 1906

illustrative of numerous cases I meet with operated upon by others, and, I am frank to admit, by myself occasionally. A conservative operation should never have been performed upon that patient. Her condition was one of chronic metritis, either as a result of a subinvolution or gonorrheal or other infection, and the slight periadnexitis was only a secondary affair. What to do with these cases does not come under the head of this discussion, but in my opinion one thing is certain: they should either not be operated upon, or if operated upon, the uterus, the prime cause of the trouble, should be removed. In the discussion that followed the reading of my paper, it was stated by one of the participants that in case of chronic metritis he could not concur in the alternative of noninterference or hysterectomy. In such cases he would curette and treat palliatively. The gentleman failed to grasp the point I endeavored to make. I was in favor of trying to benefit these cases by all the palliative means we have at hand, although curetting is seldom of much value. What I did try to emphasize was that these patients were usually subjected to two major operations, with all their risks and ordeals. If one were forced to operate upon these patients, after all palliative measures had failed, it was a mistake to attempt conservative surgery upon the adnexa, as they were not the organs at fault. It was the diseased uterus that was causing the symptoms, and would continue to do so until removed. The laparotomy for removing the one or the other adnexa would prove simply futile. I feel quite sure of my ground in this connection.

Next comes a series of cases that can scarcely, with propriety, be placed in one class, but which we must do for the purpose of a discussion of this kind. I refer to pus tubes of various sizes, with varying degrees of adhesions, and in which the ovaries are more or less involved as a result of the extensive inflammatory process that has gone before. To my mind it makes little difference in these cases as to the pathological microorganisms that were the direct etiological factors. In this I find myself differing from a leading and prominent operator who took part in a similar discussion before the New York Obstetrical Society a few weeks ago. He stated he always endeavored to do conservative surgery in inflammatory disease of the adnexa, excepting where he knew or suspected that there was gonorrheal infection. In that case he always did a radical operation. If one were to adopt that stand the cases of suppurative disease of the adnexa that would be appropriate for a conversative procedure would be very limited indeed. We all know that at least 75 per cent., roughly speaking, of the suppurative cases of the adnexa that we meet with are of gonorrheal origin. The remaining 25 per cent. of other causation than gonorrheal are usually of so serious and extensive a nature that frequently anything short of a radical operation is entirely out of the question. Further, as far as my own experience goes, the most gratifying results that I have had have been just in such cases of pus tubes of long standing, and of undoubted gonorrheal antecedents. In this class of cases also we have less fear of peritonitis following the less ideal operation (for such we must designate the conservative operation to be, at least, from a purely surgical standpoint) than in the cases due to staphylococcus or streptococcus infection.

It has been and is my custom, therefore, when operating on a patient much younger than the climacteric age to make every effort to save as much of the ovarian tissue as possible, and if feasible to do a plastic on the less diseased tube, independent of the microorganism that may have been the etiological factor. And if we be very determined to pursue such a course it is remarkable in what a number of cases we will be able to put the method into practice, that at first sight seemed unsuitable for anything short of a radical operation. Cases that looked hopeless from the standpoint of conservative surgery when the abdomen was first opened with care, patience, and, I may add, some experience, will gradually be disclosed as lending themselves to that procedure. I may have something to say of the technique later.

I have not the time at my disposal to discuss the methods to pursue to tide over acute cases of suppurative disease of the adnexa to a period when conservative surgery may be called into play. We are all pretty well agreed that acute cases lead themselves but poorly to conservative surgery, as I understand the term in this discussion. I would not designate a vaginal incision and drainage of a pus tube or an ovarian abscess as conservative surgery, that is "palliative surgery," and may be all that the case may ever require. But this discussion I fear will go far afield if we do not adhere strictly to an exact meaning of the term "conservative surgery upon the adnexa." By it I would understand the opening of the peritoneal cavity, be it through the vagina or through the abdominal parietes, and excising under the sight of the eye the most diseased structures, leaving such behind as are fairly normal, or present the prospect of restitution to the normal.

I have not had the time to investigate all the cases coming under this head that I have operated upon during the past ten years; I have, however, gone over, as well as the time would permit, the cases that occurred in my own private practice from January, 1896, to January, 1906. There were fifty-one cases. All cases of minor disease or cases of one-sided ovariotomy for ovarian cysts, or cases of ectopic pregnancy, in which conservative surgery was done, on the opposite adnexa were excluded. Some of the fifty-one cases were in acute stage when operated upon. There were two deaths. Case 1 occurred in March, 1898. It was in a young woman who had been ill for several weeks as a result of infection following a criminal abortion by a midwife. The whole pelvis was filled with irregular inflammatory masses. The temperature ranged from 101° to 104°, pulse from 120 to 130. An attempt was first made to reach the pus focus through a posterior vaginal incision, but this was unsuccessful. The abdomen was then opened, the large intestine was found covering, and extensively adherent to the pelvic organs, which were matted together into an indistinguishable mass. After separating the adhesions of the sigmoid the left adnexa were enucleated, the tube being the size of a bologna sausage, and filled with pus, the ovary completely disorganized and no ovarian tissue distinguishable with the naked eye. The tube and ovary were excised. The right adnexa were also firmly and extensively adherent to the floor of the pelvis and to the posterior aspect of the broad ligament. When they were enucleated after great difficulty some ovarian tissue was recognizable; this was left behind after cutting away the diseased tube and the disorganized portion of the ovary. The posterior portion of the uterus was raw and irregular from adhesions. The uterus was ventrofixated and iodoform gauze was packed lightly in Douglas' cul-de-sac, the end of which was carried through the

vaginal incision originally made. The patient withstood the operation poorly, but reacted fairly well later. The symptoms of septic peritonitis set in on the second day, which gradually progressed and proved fatal on the sixth day. Two criticisms readily occur to one: (1) The patient should not have been operated then, but tided over until the acute stage had been passed. It did not seem to me to be safe to wait any longer. That was over eight years ago, but I have learned better since; (2) having been forced to operate, either through the severity, threatening character of the symptoms, or through other exigencies such as the advice of other counsel, etc., a radical operation should have been done preferably through the vaginal route and with as much expedition as possible.

The second fatal case occurred in a young unmarried woman of twenty-one, who contracted an acute gonorrhea which was very virulent and extended rapidly to the tubes on both sides. For two weeks she was running high temperature, ranging from 101° to 105°, pulse 90 to 130. The pain was very severe in the right side of the abdomen, so that acute appendicitis was feared. On bimanual examination both tubes were found to be as large as the index finger and moderately fixed. A prominent surgeon was called into consultation by the family, who concurred in the opinion that an operation was imperative. On opening the abdomen both tubes were found enlarged at the outer two-thirds to the size of one's thumb. They were open and pus was flowing from the fimbriated extremities. The left ovary was excised with the tube. The right ovary was in fairly good condition, and it was left *in situ*. The appendix was adherent to the right tube, and its peritoneal coat was considerably injected. It was also excised. Drainage was carried out through the vagina. The operation seemed to have no influence for good or bad upon the patient's condition. The symptoms merely progressed. Manifestations of profound toxemia accompanied by delirium finally developed, and she died on the seventh day following the operation.

In this case I don't think it would have made much difference what course would have been pursued. It was evidently a mixed infection (although I had no positive evidence of that) which would have run a fatal course, whether it had been left alone or submitted to a radical operation. If we knew how to distinguish these cases early we might, perhaps, save some of them by timely operation, as we are able to do in cases of appendicitis. The remaining cases recovered from the operation.

A third patient (Case 3) was under observation only for two months. The menses had recurred twice, but the patient continued to suffer a good deal from abdominal pain, although the pelvic examination was negative.

A fourth patient (Case 19) failed to menstruate during the year she was under observation, although the left tube and ovary were not removed. They were bound down by firm adhesions, which were broken up. The patient was free from pelvic symptoms.

A fifth patient (Case 39) developed a cystic mass to the right of the uterus which disappeared and recurred several times since the operation. At the present time it is in abeyance. The whole pelvis was found filled with small inflammatory cystic collections at the time of the operation. The left adnexa were completely disorganized, and removed. The right seemed in fairly good condition, and was left. Menstruation has been regular, but scanty. It has been nearly four years now since the operation. A sixth patient (Case X) had ectopic gestation in the left tube (the right adnexa were excised for tuboovarian abscess) two years after the operation.

The remaining forty-three patients are practically cured and have menstruated regularly and normally since the operation. They have all been under observation or have been heard from for periods varying from two to ten years.

One patient (Case 5) became pregnant twenty-one months after the operation, and was delivered of a living child at full term. She has since miscarried twice, probably owing to a retroversion which recurred after the birth of the child, otherwise she has remained in good health. This, as far as I know, is the only case of pregnancy following the operation in the series of cases that I have presented.

In several cases of the series both tubes were filled with pus and the ovaries were extensively adherent to the intestines and the pelvic structures. In some of these so extensive was the disease that it was only the comparative youthfulness of the patient, being under twenty-five years of age, that induced me to refrain from a radical operation, which to my mind seemed to be the safer procedure, after all of the diseased structures had been enucleated and the field of operation investigated. Still the boldness of my practice was justified by the recovery of the patient, and her enjoyment of good health afterward, and by the continuation of menstruation regularly and normally.

A word or two in reference to the technique. While I have been, and am still, a strong advocate of the vaginal route, for many operations on the pelvic organs, the abdominal route, in my opinion, is the only legitimate one for the class of cases under consideration now. To carry out successfully conservative surgery upon extensive and marked disease of the adnexa requires easy accessibility, plenty of room, and good exposure to light. One needs to be in a position to be able to meet the complication of extensive injury to the intestine by careful surgical technique, as I had to do in two of my cases. In one case the tuboovarian abscess was extensively adherent to the sigmoid and had broken into the bowel by a small opening. After I removed the structures of the abscess a good sized hole in the gut had to be repaired. The patient made a good recovery.

In some of the worst of my cases, when the adhesions have been very thick and their separation has left a large, irregular, and ragged area in Douglas' cul-de-sac or on the posterior aspect of either broad ligament or of the uterus, it has been my custom to pack the area lightly with iodoform gauze and carry the end through the posterior vaginal vault into the vagina. I am aware of the tendency nowadays to discard this procedure, which is falsely termed "drainage." But I am certain many operators in this work at the present time have allowed the pendulum to swing too far. In my opinion the ultimate successful issue of conservative surgery upon the adnexa depends in a great measure upon many details in the technique, and this is something that to my mind has a great bearing.

I think we operators have a solemn duty devolving upon us in every operative case in women much under the climacteric age. We should strain every power we possess to cure our patient without sacrificing all her pelvic organs, and we should make every effort to ensure preservation of the menstrual function.

751 Madison Avenue.

THE CAUSE OF COMMON BALDNESS.*

By DELOS L. PARKER, M.D.,

DETROIT, MICHIGAN.

LECTURER ON MATERIA MEDICA, DETROIT COLLEGE OF MEDICINE

THIS report relates to an investigation of the subject of Common Baldness that has been carried on since 1887, and is still in progress.

The forms under which baldness presents itself, with extremely rare exceptions, are three in number, as follows: Common baldness (alopecia vulgaris), alopecia areata and alopecia secundaria. These forms all differ one from another in origin, symptoms, and other important particulars.

Common baldness (alopecia vulgaris) includes all cases of baldness in which the hair shedding occurs independently of any other disease, and, in addition, is limited as to its field of operation to the portion of scalp occupying the top of the head. What might be termed ordinary, every-day baldness is common baldness. Common baldness accounts for more than 90 per cent. of all cases of baldness.

Alopecia areata, on the other hand, refers to a form of baldness in which the hair shedding occurs sometimes in one, but oftener in several round or oval patches, which are located as a rule on the sides or back of the head.

Finally, alopecia secundaria is loss of hair occurring as a symptom or sequel of another disease. There are several diseases that tend to cause this form of baldness, among which are typhoid fever, scarlet fever, and erysipelas.

At different times in the course of the investigation that is under consideration, progress of the work has been reported to different medical and pathological societies. The last comprehensive report of this kind was contained in a paper entitled the "Etiology of Alopecia," which was read at a meeting of this society in June, 1901, and published in the MEDICAL RECORD in the following July.

At this time it is intended first to review, in a general way, the conclusions presented in the paper of 1901, and then, with somewhat more attention to detail, to set forth what the investigation has developed since.

In this paper the fundamental cause of common baldness was declared to be a form of respiration that leaves residual air undisturbed in the air cavities of a portion of the lungs; or, to be more explicit, since the residual air of any portion of the lungs that is not made use of for breathing purposes must necessarily lie undisturbed, and since the function of respiration can be carried on without the upper portions of the lungs being utilized but cannot be carried on without the lower portions being used, the fundamental cause of common baldness is absence of upper chest breathing.

The connection between absence of upper chest breathing and the existence of common baldness was explained in the following manner: In the first place attention was directed to the circumstance that residual air is warm, that it is saturated with moisture, that in amount it is five times greater than the tidal air, and that it contains among its constituents oxygen, nitrogen, carbon dioxide, argon and organic matter. Attention was also directed to the fact (previously proven) that whenever residual air (or what is the same thing, expired air) is kept chambered in the presence of warmth and moisture, it invariably undergoes change and develops a soluble poison that is capable, when present in the blood, of exerting a disturbing effect upon hair growth.

With this introduction it was explained that absence of upper chest breathing is the fundamental cause of common baldness, because it establishes conditions that permit the above-mentioned soluble poison to be formed from the residual air contained in the air cavities of a portion of the lungs, whence by a process of absorption it is taken up by the blood and is thus placed in position to exert its specific effect.

That a poisonous substance circulating in the blood should limit its destructive action to the hair of the top of the head, as must be the case if the theory that is being considered is correct, was explained by the statement that the roots of the hair of the top of the head, by reason of lying over the hard, glistening and practically bloodless occipitofrontal aponeurosis, are deprived of the nourishment that the roots of the hair of other portions of the head and of the face derive from the soft, blood-saturated muscular tissue with which they are in close relationship; and as a result the hair roots of the top of the head are of comparatively low vitality.

In support of the contention that absence of upper chest breathing is the fundamental cause of common baldness evidence was presented that had been derived: (1) From observing cases of common baldness; (2) from treating cases of common baldness; (3) from experimenting on animals.

Observation.—It was stated that an observation extending over a period of many years and applied to thousands of persons had developed not a single exception to the rule that persons affected with common baldness do not employ upper chest breathing, while those not affected with this disease as regularly do employ this form of respiration. It may be added that during the years intervening between the time the paper was published and the present no exception to this rule has been discovered.

Results of Treatment.—In describing the evidence derived from treating cases it was stated that during a period of ten years successive groups of persons had been treated for common baldness by means of directions to practice continuously upper chest breathing. These persons followed the directions they had received with widely differing degrees of thoroughness. Some followed their instructions to the letter, others not at all, and still others to different degrees between these extremes. The results received from the treatment were described as being satisfactory in direct proportion to the thoroughness with which the treatment had been applied. The results from a case in which the treatment had been followed closely were described as follows: After one week dandruff, when present (and this affection is present in about 80 per cent. of all cases of common baldness) entirely disappeared. At this time, too, the hair, which is frequently either dry and harsh, or unusually oily when common baldness is present, assumed a natural appearance. Then some weeks later, usually five or six weeks from the time of starting the treatment, new hair began to make its appearance. The new growth as a rule appeared first among the hairs about the margins of the bald areas, and after multiplying there invaded the bald patches by extension. The new hair growth, even after being well started, developed slowly, so that months or even years were passed before even a moderately sized patch of uncovered scalp became covered with new hair. In all cases any interruption in applying

*Read at a meeting of the Detroit Academy of Medicine, September 11, 1906.

the treatment was accompanied by a corresponding interruption in the progress of the case toward recovery. As a result of treatment that involved nothing but the continuous performing of upper chest breathing it was declared that hair had been seen to appear on portions of scalp that had been bald for upward of twenty years.

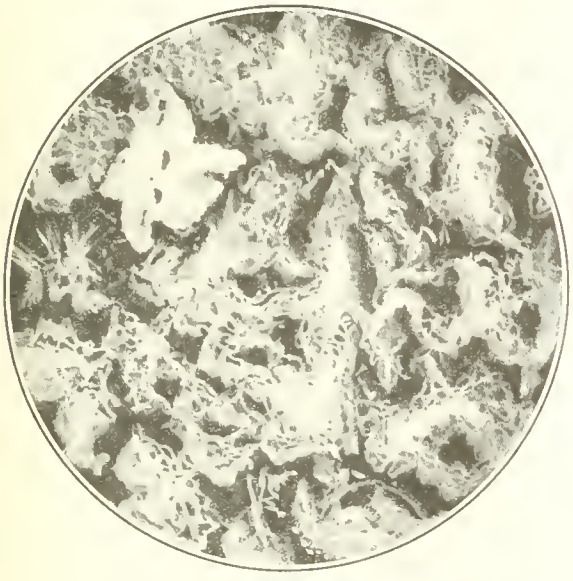

Fig. 1.—Material isolated from expired air. ×5.

Results of Experiments Applied to Animals.—These experiments were based on the supposition that if expired air should be kept chambered in the presence of warmth and moisture outside the lungs, it would undergo the same change as when kept under the same conditions within the lungs; and that the products resulting from such change injected artificially into the blood of animals, would exert the same effect upon such animals as would have been the case had these products been absorbed by the blood from the lungs.

Accordingly a two-liter (half gal.) flask was sterilized and filled with distilled water. When this had been done all but a small portion of the water in the flask was displaced with expired air. This was accomplished by having two glass tubes of unequal length passed through the stopper of the flask, after the manner of those of an ordinary laboratory wash bottle, and crowding the water out by forcing expired air either directly from the lungs, or from a rubber bag, into the flask through the shorter tube.

When charged with expired air and a small amount of water, the flask was closed by connecting together by means of a piece of rubber tubing the outside ends of the tubes, then agitated so as to bring the inclosed water and expired air into close relationship (in imitation of the conditions that prevail in the lungs) and finally kept at body temperature in an incubator. Ten days were allowed for the change in the expired air to take place.

When the flask was placed in the incubator the expired air within, both as to condition and surroundings, was very similar to residual air left undisturbed in the lungs. Moreover, after the flask had been in the incubator some hours this similarity became more marked by reason of the circumstance that drops of water gathered upon the inner surface of the flask to such an extent that the air within was in contact only with a wet surface. In these circumstances it could be affirmed that the principal difference between the expired air chambered in the flask and the same air chambered in the lungs lay in the fact that in one case the air was held in a single cavity, while in the other it was held in a great number of small cavities. An attempt was made to overcome this difference by agitating the flask occasionally so as to bring all parts of the air in contact with the water. This maneuver also made it certain that any soluble material in the expired air, whether there originally or whether formed by reason of the expired air's being in a warm and moist place, would become dissolved in the water.

The animals used for the experiment consisted of dogs, hens, and pigeons. The injecting material was the water that had been kept in the flask with the expired air. This water in appearance differed in no respect from ordinary distilled water. It was colorless, odorless, neutral in reaction, and apparently of the same specific gravity as when placed in the flask. It was found also not to deviate polarized light.

In making the injections the flask was first agitated and then from 5 to 10 c.c. (1¼ to 2½ drams) of its inclosed water injected with an ordinary serum syringe beneath the skin of each animal. This was done once a day and continued for five months. At the expiration of this time the hens and pigeons had lost completely their coats of feathers, while in the case of the dog, the abdomen, sides, and hind legs had become denuded of hair. During the time they were being treated the animals showed no signs of disturbed health, and in six weeks after the injections had been discontinued all had gained new coats to take the place of those lost.

In addition to these experiments other like animals were treated with other substances closely related to the preparation already described. In one case water from a flask in which atmospheric air was made to take the place of expired air, was used. In another case, distilled water by itself constituted the injecting material. And in still another case, water impregnated at the time the injection was made with freshly expired air, was used. In this instance the injection was the same as that of the experiment first described, except that the flask was not placed in the incubator and no time was allowed for change to occur in the expired air.

Fig. 2.—Another field of same material shown in fig.

The injections in these control experiments were

given daily and continued five months. At the time they were discontinued no effect of any kind had been observed in any of the treated animals. These control experiments showed that in the first experiment described above the shedding of hair and feathers had been caused not by the water as such, nor by the expired air as such, but by some-

FIG. 3.—Pigeon above received injections of material from expired air not soluble in absolute alcohol; pigeon below received injections of material from the same source soluble in absolute alcohol; the results are shown in Fig. 4.

thing that had developed in the expired air during the time it had been in the incubator.

The skin coverings of fur-bearing animals, such as guinea-pigs and rabbits, were found not to be affected by injections of the material that caused the shedding of the skin coverings of the animals above mentioned. There is an anatomical reason for this that need not be explained at this time. It is only necessary to state that fur differs in many important particulars from both hair and feathers.

As to the nature of the change that takes place in expired air when such air is chambered in the presence of warmth and moisture, nothing at the time the paper was published had been determined; but as organic matter is a constituent of expired air, and as organic matter is prone to undergo decomposition when kept moist and warm, the change was considered (without warrant, however), to be putrefactive in character, and the organic matter of the expired air the material acted upon.

The paper that is being considered coincided in point of time of appearance with the concluding of the experiments above described.

In the closing portion of this paper the following words were used: "The results of the experiments just described show that when expired air from human beings is kept chambered in the presence of warmth and moisture long enough for decomposition of its organic matter to take place, there is developed a substance, which, when introduced into the blood of certain animals, exerts a selective poisonous action upon the hair, or tissues analogous to hair, with which such animals may be endowed, and that beyond this, so far as careful observation can determine, it produces no effect whatever."

Trichotoxin.—With the existence and action of the substance under consideration demonstrated, the need of a word, to take the place of a phrase or sentence, in making reference to the substance itself, is apparent. To meet this want, the writer presents "Trichotoxin," from the Greek θρίξ hair, and ἰοξικόν poison. So much for the paper published in 1901.

Since that time the work of the investigation has been devoted chiefly to the study of the agent to which the name trichotoxin had been given. The work itself represents a series of experiments carried on partly in the bacteriological laboratory of the Detroit College of Medicine and partly in the Detroit Clinical Laboratory. The first task undertaken in this connection consisted of an effort to isolate trichotoxin from its aqueous solution.

As has been said, the agent at this time was looked upon as a product formed by putrefactive changes taking place in the organic matter contained in expired air, or, in other words, as formed by bacteria acting upon such organic matter. This view made it necessary to consider the possibility of the agent's being a ptomain.

A ptomain, as defined by Vaughan and Novy (*Cellular Toxins*, 1902, p. 29), "is an organic chemical compound, basic in character, and formed by the action of bacteria on nitrogenous matter."

In undertaking to isolate trichotoxin as a ptomain it was found that there are several methods of extracting ptomains. The so-called Stas-Otto method was used. This was applied by placing 60 c.c. (about two ounces) of water containing trichotoxin, previously rendered slightly alkaline with sodium carbonate, in a separatory funnel with an equal

FIG. 4.—Pigeons shown in fig. 3 after three and one-half months of treatment.

amount of pure ether. When this had been done, the funnel, tightly stoppered, was agitated for some time and then left to stand twenty-four hours to allow the fluids to separate. When this had taken place the water was drawn from the funnel and the ether transferred to an open glass dish and allowed to evaporate spontaneously. When this had oc-

curred the bottom of the dish was found to be covered with a thin, tightly adherent residue much resembling a light coating of frost on a window pane. To determine whether or not this residue contained trichotoxin, the whole deposit was redissolved in distilled water and introduced by means of small daily injections beneath the skin of a small

Fig. 5.—Trichotoxin crystals. × 87.

bird. As a result of this procedure at the end of six weeks the bird had lost completely its coat of feathers. This experiment showed that trichotoxin can be extracted from watery solution by ether, and also that it exists as a solid.

It did not, however, prove trichotoxin to be a ptomain. Many substances not ptomains can be extracted with ether. It showed that the possibility of the agent's being a ptomain still existed, and that the applying of further tests was in order. Accordingly, reagents considered capable of precipitating ptomains from aqueous solutions were added to different portions of the preparation that was being tested. Potassio-mercuric iodide, potassium iodide, mercuric chloride, picric acid, sulphuric acid, tannic acid, and phosphomolybdic acid were used. None of these reagents caused a precipitate to appear.

Efforts were then made to demonstrate the presence in the liquid of the bacteria that should be there in case a ptomain was present. The liquid was centrifugalized and examined, both in thin layer and in a hanging drop, with the aid of a microscope provided with a 2 mm. (1-12 inch) oil immersion objective. This procedure brought no bacteria to light.

Next, portions of the centrifugalized liquid were evaporated to dryness on cover glasses and the residues thus secured stained, one with Löffler's methylene blue, another with cold aqueous fuchsin, another with cold carbol fuchsin, and a fourth with hot carbol fuchsin. An examination of these products with a high power oil immersion objective did not disclose the presence of bacteria.

Finally an experiment was undertaken to determine whether or not expired air, from which trichotoxin is developed, contains bacteria.

This was done by keeping at body temperature two flasks, one containing sterile agar and atmospheric air, the other sterile agar and expired air. The results were as follows: In a few hours colonies of bacteria developed on the surface of the agar in contact with atmospheric air, which in a few days were in sufficient quantity to render the whole of the agar cloudy. In the other flasks, on the other hand, the agar remained unchanged for two weeks. This showed that so far as the ordinary bacteria of atmospheric air are concerned, expired air is practically sterile.

The results of these tests, taken as a whole, proved trichotoxin not to be a product resulting from the decomposition of the organic matter of expired air, a finding that made it necessary to abandon the idea of its being a ptomain.

Trichotoxin is Non-Volatile.—Coincidently with the performing of the experiments just described, others of a different character were carried on. In one a bird was treated with daily injections of trichotoxin-bearing liquid that had been left for some time in an open dish. This bird lost its feathers as promptly as those treated with material from closed receptacles. This showed trichotoxin to be a nonvolatile substance.

Trichotoxin Given by the Mouth is Inert.—In another, a bird was permitted to drink nothing but water charged with trichotoxin for a period of several months. No effects of a disturbing nature followed. This showed that the characteristic effects of trichotoxin cannot be secured by introducing the agent into the system by way of the stomach.

Trichotoxin May Be Isolated by Evaporation.—Returning to the isolating of trichotoxin, when this substance was found to be nonvolatile the idea at once presented itself that it might be isolated by evaporation. Accordingly, water was charged with trichotoxin in the usual way and then evaporated to dryness on a water bath. As a result the bottom of the dish used to hold the liquid was found to be thinly covered with a residue appearing in all respects but color like the residue obtained when ether had been used to extract trichotoxin. The evaporation product was yellowish in color. This residue was redissolved in water and shown to contain trichotoxin by the results obtained from its use in treating pigeons.

Thus the efforts made to isolate trichotoxin had

Fig. 6.—Trichotoxin crystals × 87.

discovered two methods of accomplishing this result, one by using ether, the other by evaporating the mother liquor to dryness. The latter was found to be the more satisfactory on account of its greater simplicity. The residue obtained by evaporating the mother liquor, as said above, resembles frost on a window pane except that it is tinted yel-

low. Viewed under a microscope with a 16mm. (2-3 inch) objective, which magnifies 87 diameters, the deposit was found to consist of different-shaped crystals, with a waxy substance either clinging to the crystals, or lying in separate masses. Figs. 1 and 2 represent different fields of the same deposit as seen with the microscope.

Trichotoxin Does Not Develop Singly.—After inspecting its external appearance an effort was made to learn something of the behavior of the residue under the influence of different reagents. With this end in view, scrapings of the substance were placed on glass slides, and with the aid of a microscope were watched while different reagents were applied to them. As this continued nothing occurred to attract attention until absolute alcohol was used. When this substance was brought in contact with a specimen of the deposit, part of the crystals disappeared in solution and part remained unacted upon. This showed that an original deposit of the material contains at least two constituents, one soluble, the other insoluble, in absolute alcohol. This information also raised the following questions: Had the specific effects that had followed the injecting of the material into animals

Figs. 1, 2.—Trichotoxin crystals. × 87

been caused by one of these constituents, or by their combination? And if by one of them, which was the one? Manifestly there was but one way to secure answers to these questions. This was to treat different animals with the different constituents and note the results. This plan was adopted and carried into effect.

Two pigeons were made the subjects of the experiment the work called for (Fig. 3). The pigeon occupying the upper position in the illustration was treated with a watery solution of the body not soluble in absolute alcohol, the other with a like solution of the body soluble in alcohol. The injections were made once daily, and continued for a period of three and a half months. At the expiration of this time the pigeon receiving the substance not soluble in alcohol had lost completely its coat of feathers, while the other was unaffected, so far as losing its protective coat was concerned (Fig. 4). Thus it was shown that of the two known constituents of the material that had been employed to destroy the skin coverings of animals in previous experiments, only the body not soluble in absolute alcohol had exerted a destructive effect on the skin appendages of such animals. It was shown also that the word trichotoxin, taken in the sense in which it had been adopted, should apply to this constituent alone, and not to the combination of substances it had previously been employed to designate.

Figs. 5, 6 and 7 represent different fields of the material not soluble in alcohol (trichotoxin) as seen with the aid of a microscope magnifying 87 diameters. The heavier shaded parts seem to be composed of the waxy material mentioned above in connection with the description of the original deposit, while the crystalline portions resemble spicules of newly formed ice. Whether the crystals and the waxy part are different forms of the same substance, or are different substances with different properties, has not been determined. In the form in which it is here represented the product is permanent in the air. Specimens have been kept for months on glass slides without cover glasses without undergoing appreciable change in appearance.

The body soluble in alsolute alcohol has been named "stearotoxin." Its properties will not be considered in this paper.

When the pigeon that lost its feathers in the last experiment had served the purpose mentioned above it was made the subject of another experiment for the purpose of learning if absence of feathers for a considerable time tends to delay the forming of a new crop. By means of repeated injections of trichotoxin the bird was kept denuded of feathers for a period of six months, when, upon discontinuing the injections, a new crop of feathers developed as promptly as had been the case in any of the experiments already described. In this way it was shown that the structures that develop the skin covering of birds may be subjected to the action of trichotoxin for a considerable length of time without suffering permanent injury.

Time Required for Trichotoxin to Develop.—By means of experiments information was gained concerning other points in the inquiry as follows: By evaporating at short intervals successive specimens of water kept in contact with expired air, and examining microscopically the residues thus secured, it was found that expired air kept chambered at body temperature, begins to develop trichotoxin in about six hours, and that the process is completed, so far as a fixed amount of expired air is concerned, in four or five days.

Proportion in Which Trichotoxin Develops.—By placing a known quantity of expired air—240 liters (about 60 gallons) being the amount—under conditions that favor the forming of trichotoxin, it was found that one liter of expired air developed Gm. 0.0003 of trichotoxin, and Gm. 0.000054 of stearotoxin; or, to use a different standard, one gallon of expired air developed grain 1-53 of trichotoxin, and grain 1-300 of stearotoxin.

The Constituents of Expired Air That Develop Trichotoxin Soluble in Water.—By forcing air directly from the lungs through a glass tube placed so that the air rose in bubbles through a column of distilled water, it was found that the water takes from expired air the constituents that are converted into trichotoxin, and that water thus treated develops trichotoxin even when kept in an open receptacle.

Reagents That Precipitate Trichotoxin.—As a result of efforts made at different times during a period covering several months it was finally found that trichotoxin may be thrown out of its aqueous solution by adding any of the following reagents: Barium chloride, barium sulphide, barium nitrate,

barium hydrate, barium dioxide and strontium nitrate. The barium preparations vary with respect to the amount of precipitate they cause to appear. They are arranged here in the order of their activities, the most active being first. Strontium nitrate corresponds in precipitating power to the most active of the barium preparations. Calcium and magnesium, the other members of the alkaline earth group of metals, so far as tested, do not form a precipitate when added to a watery solution of trichotoxin.

By utilizing a precipitating reagent the finding previously made, that under favorable conditions a fixed quantity of expired air begins to develop trichotoxin in about six hours and completes the conversion in four or five days, was confirmed.

Warmth Not Essential to the Forming of Trichotoxin.—That expired air does not necessarily require the presence of warmth in order to undergo the change requisite to the forming of trichotoxin was brought out by finding that the different reagents that precipitate trichotoxin, upon being added to water charged some days previously with expired air, cause a precipitate to appear even when such water has not been subjected to heat.

Water from a laboratory wash bottle that has been in use for some time has as a rule absorbed enough expired air to give this reaction. It is altogether probable, however, that the presence of warmth not only hastens the forming of trichotoxin, but also tends to make the process of conversion more complete.

Present Status of the Investigation.—At the present time the attempt is being made to clear up two of the more important points of the inquiry that remain undetermined. One involves the determining of the chemical formula of trichotoxin; the other, the ascertaining of the nature of the change that expired air undergoes when trichotoxin is developed. The first of these tasks, that of finding the chemical formula of trichotoxin, is under the direction of W. H. Allen, Ph.G., while Thaddeus Walker, M.D., and Joseph Sill, M.D., of the Detroit Clinical Laboratory, are aiding in the endeavor that is being made to accomplish the second. It has already been found that when expired air has been heated to 80° C., the temperature at which practically all known ferments are destroyed, it cannot be made to yield trichotoxin. Also that when water charged with expired air has a large surface exposed to the atmosphere, it develops trichotoxin more readily than when it has only a small surface thus exposed. These two facts seem to show that the change referred to is dependent on the action of an aërobic enzyme. Other tests must be applied, however, before a definite conclusion in regard to this point can be reached.

The work of analyzing trichotoxin was begun some months ago, and thus far has consisted chiefly of efforts to secure material in sufficient quantity to meet the demands the work imposes. For this purpose a specially constructed apparatus has been devised. This consists of a 36 liter (8 gallon) crock, a bell-jar, an iron table, and a bunsen burner, all arranged as in Fig. 8. In using the apparatus the crock is filled with distilled water, the bell-jar, open at top, submerged in the water, and the burner lighted and the flame regulated so as to keep the water at a temperature of 37° C. (98½° F.). Next a glass tube, bent at a right angle at one end and connected with a piece of rubber tubing provided with a glass mouthpiece at the other, is passed down between the side of the crock and the bell-jar and turned so as to bring the end beneath the bell-jar. When this has been done, as many persons as can be secured, are assembled and one after another directed to force air directly from the lungs through the tube. While this is being done the vent at the top of the bell-jar is kept open until all but three or four of the persons have forced expired air through the tube, when it is closed. By proceeding in this way a comparatively large volume of expired air is made to bubble up through the water, and by so doing to give up to the water a greater or less portion of its convertible constituents, while in the end the bell-jar is left filled with expired air resting in contact with the water. In concluding the charging operation the glass tube is removed and the crock screened from dust by means of a cloth cape.

For a period of five months the apparatus was

Fig. 8.—Apparatus for developing trichotoxin from expired air.

charged and recharged with expired air at intervals of eight or ten days, and the water in the crock then evaporated to dryness. The residue thus secured, containing both trichotoxin and stearotoxin, weighed Gm. 0.807 (grains 13.38). When split up with absolute alcohol, the trichotoxin thus secured weighed Gm. 0.718 (grains 11.08), and the stearotoxin, Gm. 0.149 (grains 2.30).

This yield of trichotoxin is now available for the purpose of the examination. The apparatus will be kept in constant use, however, in the hope that a deficiency of material may be avoided.

Summary.—From what has been written above it will be seen that the theory discussed in this paper makes common baldness depend for its existence on a double cause, one being the remote or fundamental cause represented by the absence of upper chest breathing, a condition that allows a poisonous substance to develop in the lungs; the

other, the direct or exciting cause, represented by the effect produced by this poisonous substance circulating in the blood.

Conclusion.—The evidence here submitted in support of the theory that absence of upper chest breathing is the fundamental cause of common baldness cannot yet be said to be complete. Its real value has not been demonstrated to be that of its face value. Before its real and face values can be said to correspond, the evidence itself must be vouched for by many times more than one person. That this condition of affairs was bound to prevail was fully understood when the task of preparing this paper was entered upon, a circumstance that caused the attempt to be made so to describe any evidence made use of that the testing of its value might become as simple a matter as possible.

550 Jefferson Avenue

SOME POTENT ETIOLOGICAL FACTORS IN BACKWARD CHILDREN.*

By M. NEUSTAEDTER, M.D., Ph.D.,

NEW YORK.

Much stress has been laid upon such physical defects as enlarged tonsils, adenoids, refractive errors, and carious teeth, as the most prominent etiological factors in backward children. But when we survey the statistics and find on the one hand 85 per cent. of all school children are suffering from some physical ailment, and among the sufferers 95 per cent. are bright pupils, when we think of the vast army of graduates who yearly leave schools and in spite of their physical defects become bright men and women, and we are reminded by history that such great men as Rousseau, Kant, Mendelssohn, Darwin, and others were physically incapacitated, that great singers suffer from incurable diseases of the vocal cords, and on the other hand some of the most vicious children whom I have personally examined presented no physical defects that I was able to detect, it seems to me to be imperative that we look further than tonsils and other physical defects. Apart from the fact that with the adenoids and enlarged tonsils out of the way, every pupil is not yet supplied with pure air in his badly-ventilated dormitory nor provided with wholesome food, we have to contend with other factors that are far worse and create greater havoc in the physical and mental make-up of the child, than all the physical defects combined. These defects are certain drug habits to which all these backward children are addicted.

After having carefully studied ninety-five cases of backward children between the ages of ten and sixteen years in one school, without any prejudice as to the etiological factor or factors, I have come to the conclusion that it is the addiction to alcoholic stimulants or strong decoctions of tea or coffee, or to the smoking of cigarettes, or to a combination of two or all the poisons enumerated, that far outweighs in importance as etiological factors all the physical defects combined.

Before going into a discussion of the physiological action of these drugs, permit me to pass a review of the examination of the ninety-five backward children mentioned. Of these (the figures representing percentages) 22.8 were badly nourished, 66.5 had enlarged cervical glands, 1.0 had chorea, 3.8 were suffering from cardiac disease, 1.9 were suffering from pulmonary disease, 2.7 had skin disease, 0.95 deformity of the chest, 32.3 had defects of vision, 28.5 had defects of the ear, 9.5 had nasal defects, 34.2 had bad teeth, 2.7 had deformed palate, 20.9 had enlarged tonsils, 71.25 had bad mentality, 6.6 were drinking strong decoctions of tea or coffee, 3.8 were drinking coffee and smoking cigarettes, 36.1 of all and 98 of boys were addicted to the use of tobacco, coffee, and alcoholic stimulants, 25.65 were addicted to the use of tea and beer, 1.1 claimed to have partaken of none of these drugs, 16.1 had no physical defects at all, 54.0 had a two-inch chest expansion during the act of respiration, 18.0 had three-inch expansion, 12.0 had one-inch expansion, 90.0 were underweights.

These statistics speak for themselves. I then examined seventy-two pupils of the same school whom the teachers termed the brightest, and found total abstainers 7.2, users of tea 5.6, of coffee 23, of beer 0.72, of tobacco 4.3, of tea and coffee 8.6, of coffee and beer 11.5, of tea, coffee, and beer 0.72.

Let us now consider the effects of alcoholic stimulants: The experiments of B. W. Richardson, Dogiel, and others indicate that alcohol, even in very small quantities, affects protoplasm, and therefore the entire system. It tends to cause cessation of the ameboid movements of the leucocytes, destroying their function. These are driven in masses by increasing rapidity of the heart's action and become blocked in the capillaries, forming centers of obstruction and injury.

Prout, Edward Smith, Harley, Schmiedeberg, Vierordt, Kerr, and others have proved that alcohol lessens the absorption of oxygen by the red blood corpuscles and the exhalation of carbonic oxide. It favors the growth of many pathogenic organisms, including those of pus and diphtheria; Lancereaux enumerates cases showing marked inhibitory influence of alcohol on the growth of children, and in my ninety-five cases we had 99 per cent. of underweights. It inhibits or even entirely destroys the food-dissolving action of the gastric juice. Inflammation of the mucous membrane of the stomach, with increased secretion of a thin tenacious mucus and a loss of secreting power, as a result of the ingestion of alcohol, is known to every one. The appetite becomes impaired or even lost. Ptyalin of the saliva and pepsin are precipitated, the gastric vasodilators are paralyzed, while the constrictors are stimulated, preventing the flow of gastric juice and accounting for irritability, anorexia, etc. Duodenal and pancreatic function is prevented. Stearin is dissolved out of the fat by alcohol, and remaininig elements are contributing to fatty degenerations of various organs. Wilkins holds that the continued use of alcohol will prevent the rehydration of glycogen and its transfer to the blood and oxygenation of bilirubin to form biliverdin. In this sense even small quantities of alcohol are inimical to life.

That the liver suffers organic changes from the continued use of alcohol is well known to us. Lancereaux reports the findings of an histological examination in two rabbits, which were subjected to small doses of wine. There were traces of an irritating influence upon the liver, which were found principally in the central parts of the lobes. The connective tissues of the portal spaces did not present lesions that were very clear, but the subhepatic veins and the capillaries were filled with leucocytes and proliferated endothelial cells. The glandular parenchyma was remarkable for the considerable size of its nuclei, which were vesicular; the cellular protaplasm seemed to be intact. One had died at the end of twenty days, without presenting any visceral alterations. The other had died after thirty days, and presented hemorrhage of the stomach.

*Read before the Society of Medical Inspectors of the City of New York, December 4, 1906.

The liver was of a pale-grayish color and the spleen was tumefied.

The intestinal tract bears the brunt of the irritating action of improperly digested food, and this condition is frequent, especially in children. Koplik claims that many children suffering from acute or subacute gastrointestinal disease are the victims of unrestrained administration of alcoholic stimulants. Wintz and Hudelo hold that the ingestion of alcohol causes migration of microbes from the intestines to the peritoneum and to the blood of the vena porta.

The habitual ingestion of alcohol interferes with the functions of the kidney structures and the products of metabolism are retained in the system. The various forms of nephritis are the natural consequences of the irritation produced. Glaser observed that uric acid and calcium oxalate crystals are found in the urine of persons in good health after taking alcoholic drink, besides an increased number of leucocytes with cylinders and cylindroids. From this premise we may conclude that, even in moderate quantities, alcohol irritates the kidneys, the augmented leucocytes, cylinders, and crystals being due either to the increased metabolism of the tissues or an alteration by alcohol of the relations of solubility of urine salts.

The direct action of alcohol upon the involuntary muscular system would indicate that the heart muscle and blood-vessels will suffer on account of their continuous overdistention. By lowering the vitality of the entire system, alcohol exposes its victim to the danger of tuberculous infection of the lungs. It is a well-known maxim to even the recent college graduate that the prognosis of pneumonia in one addicted to the use of alcohol is invariably bad. Tharain holds that one of the most efficient prophylactic measures against tuberculosis would be the repression of alcoholism, and Lagneau states that the increase of tuberculosis is proportionate to that of alcoholism in France.

As regards the action of alcohol upon the nerve tissue and cells: (1) It changes the granular matter of the nerve cell, breaking up its nutrition and thereby inhibiting its dynamic force. (2) This action is followed by contraction and atrophy of the dendrites, shrinking of cell walls, as in fatigue; and coalescense and disappearance of the granular protoplasm. (3) The special injury from alcohol seems to be in protoplasm and terminal fibers of nerve trunks: the irritation and inflammation of the nerve walls and fibers ending in sclerosis are common. There is a marked sensorial palsy and a slowing of all mental operations. The use of alcohol produces an apparent temporary increase of brain activity, which is but an evidence of its paralyzing and deleterious effect. It destroys the special functions of the cerebellum and produces tremor and weakness of the lower limbs. Rust states that a large percentage of insanity in children in Germany is due to habitual drinking.

Mental disorders and crime are shown by statistics to have in alcohol one of their most potent etiological factors. J. J. Ridge shows that from one-fourth to one-third of the lunacy of the United Kingdom is the result of the custom of drinking alcoholic liquors, and in every country where the habitual use of alcohol prevails there is an increase in lunacy and degeneracy. The literature of the past three years has fully demonstrated that fact. Neurological and pathological, together with recent experimental work, show that in the early stages of the insanities there is a profound nutritive and dynamical failure in the nerve elements of the brain, which finds expression in the insomnias, the melancholias, and the commencing loss of memory, with easily induced mental fatigue which their subjects experience and the pathological facts ascertained insofar as they afford any light, force on us the conviction that we are dealing with serious nutritive and dynamical changes in the central nervous organ.

The manner in which the pathological lesions and the symptoms correspond with one another is as follows: The sensory disorders, the exaggeration of the sensibility of the skin, the anesthetic troubles, and the ocular and auditory disorders would correspond to the beginning of the vascular disturbances, when the nerve cells, irritated by an insufficient supply of proper nutriment, the presence of a poisonous stimulus, overact for the time; then, as nutriment is still withheld from them, altered metabolism results. The beginning swelling of the dentrites of the sensorimotor region is marked by paresthetic symptoms, those of the purer sensory region by visual and ocular troubles, and some amnesia, especially for recent events; or, in other words, cells that have the function of evolving and transmitting thought cannot work properly, and defective memory results; later, as the motor cells are more and more involved and nuclear changes begin, continuous tremor becomes apparent, the muscles no longer coordinate perfectly, unless for a moment under the direct influence of the will. Still later, when a portion of the cell structures have become highly degenerated and the altered cells have become more numerous, the already tottering will-power becomes more and more deadened, memory and judgment fail, and when the degenerative process is far advanced an incomplete dementia is the final result.

Alcohol is a narcotic poison, its food value under ordinary conditions is practically nil, and put in the most advantageous light can only be temporary, and then of an exceedingly slight and wasteful character.

The injurious effect of tobacco upon the system is admitted even by the habitual smoker, and it is my aim to show the extent of the injury and manner in which it affects the system of the child and thereby constitutes an etiological factor in his backwardness. The physiological effects of tobacco are exerted through its alkaloid, nicotine, and the alkaloids produced by the combustion of the tobacco and its destructive distillation in the act of smoking, such as pyridine, callidine, picoline, and an oil. It acts especially on the spinal and sympathetic system of nerves as well as, in a minor degree, upon the cerebrum and cerebellum, the nerves of special sense, the medulla oblongata, and the vasomotor system producing slight stimulation at the beginning, followed soon by a depression. Many a smoker remembers the first "smoke," followed by vomiting, dizziness, profuse cold, clammy perspiration, diarrhea, sense of alarm, and feebleness of pulse. These effects become lessened as the habit of smoking is acquired. The physically healthy child, addicted to its use, loses the power of resistance; how much more harm then is done to the child with physical defects already established? We are familiar with effects of other poisons ingested in small quantities for a long period of time, such as lead, mercury, arsenic, iodine, etc., and we hardly doubt that tobacco will produce a deleterious effect upon the organism. Various experiments, recorded in medical literature, show that the presence of the alkaloids of tobacco in the system diminishes the amount of feces, lessens the quantity of urine and the amount of uric acid, phosphoric acid, and sulphuric acid

eliminated through the lungs, and that retrograde metamorphosis is stopped. This shows conclusively that tissue waste is excessive, especially the waste of nerve tissue is shown by the increased elimination of phosphorus.

Grasset and Parentz have studied the physiological action of nicotine oxalate, which is eight times less toxic than nicotine. The constant symptoms were contractions of the pupils, paralysis and convulsions, salivation, cerebral anemia, peripheral vasomotor constriction and cardiac asystole. Not only does tobacco produce insomnia, but it renders sleep less deep, and consequently less refreshing. The result of an inadequate amount of refreshing sleep is to render the child irritable and heavy during the day, and the feeling of lassitude and incapacity for intellectual work is especially pronounced during the forenoon. Tobacco acts as a cerebral irritant, and interferes with the vasomotor centers of the brain to such an extent that the vessels are unable to adjust themselves forthwith to the condition required for healthy and untroubled sleep. Every smoker is aware that a change of tobacco or a strong cigar will rob him of his sleep.

A careful study of this subject by Dr. J. W. Seaver of Yale, based upon the observation of one hundred and eighty-seven students during their first and final college years yields the following results: He claims that the nonuser of tobacco increased 10.4 per cent. more in weight than the regular user, and 6.6 per cent. more than the occasional user. In growth the nonuser increased 24 per cent. more than the regular user, and 14 per cent. more than the occasional user. In the increase in chest measurement, the nonuser had an advantage over the regular user of 26.7 per cent., and over the occasional user of 22 per cent., but in capacity of lungs the growth was in favor of the nonuser by 77.5 per cent. when compared with the regular user, and 49.5 per cent. when compared with the occasional user. He concludes that tobacco has a dwarfing effect, and he is corroborated by Prof. Hitchcock of Amherst College, who has published the following: Of the class of '91 75 per cent. increased in their measurements and tests during the whole course, while 29 per cent. remained stationary or fell off: In separating the smokers from the nonsmokers, it appears that in the item of weight the nonsmokers increased 24 per cent. more than the smokers; in height they surpassed them 37 per cent., and in the chest girth 42 per cent.; in the lung capacity there was a difference of 8.36 cubic inches (about 75 per cent. in favor of the nonsmokers), which was 3 per cent. of the total lung capacity of the entire class.

The knowledge of the pathological effects of tobacco is rather meager. The only anatomical lesion claimed to be due to the effect of tobacco is that incidental to a chronic form of retrobulbar neuritis of the optic nerve, which generally affects both nerves and is caused by certain poisons, chief among which nicotine has been claimed to be an efficient factor. Dr. G. E. De Schweinitz, in his treatise on the Toxic Amblyopias, includes this substance among the etiological factors. In Germany this is regarded as the most potent agent. The result, then, of our study of tobacco as a factor in the production of functional or organic disorders is that the use of tobacco by children retards not only their proper physical development, but also their mental progress.

The coffee bean, when green, contains caffeine, caffeotannic acid, and, according to Palladine, an alkaloid caffearine. During the roasting process, however, a volatile oil is developed, which with other substances is collectively termed "caffeone." Besides there remain some astringent acids, as caffeotannic acid, and caffeic acid. The empyreumatic oil modifies the action of the coffee bean, inasmuch as before roasting, caffeine alone acts. Marshall, Hare, and T. Lauder Brunton have studied the action of the empyreumatic oil of coffee and report that 11.6 per cent. of oil is obtained from an average browned bean; in consequence, an ordinary breakfast cup of coffee contains about 45 minims of the oil, provided all the oil in the coffee used is extracted. In their opinion the oil directly increases cardiac action in small doses and depresses it in large doses. On the spinal cord of the frog it causes increased reflex activity, but on the mammal with a well-developed brain, drowsiness and sleep. Cohnstein and Gaetano Vinci have formulated the following conclusions with respect to the physiological action of coffee: (1) In small doses caffeine increases arterial pressure while a larger amount prevents this increase. (2) The influence upon the blood pressure is the result of the changed condition of irritability of the vasomotor center, caused by caffeine. (3) It has a direct action on the heart, showing itself in the pulse-frequency and wave-height, first as an irritant and then as a paralyzant. (4) The heart muscle is affected by caffeine in precisely the same manner as the skeletal muscle.

Pavinski holds that caffeine exerts its stimulating action chiefly on the nervous system and Germain Sée and Lapicque concur in this view that muscular labor is affected only inasmuch as the corresponding cerebrospinal center is affected and not the muscle itself. T. Lauder Brunton and Bennet contend that its effect on the spinal cord is in lessening the conducting power of the sensory columns of the cord. This they proved by irritating the posterior roots of the cord before the injection of caffeine into the circulation; this caused violent struggles and loud cries; a like irritation after the injection caused only a slight quiver. This is the characteristic difference between the action of caffeine and theine, the alkaloid of tea. The first acts most prominently on the sensorium, while the latter acts on the motor tract. Irritation of the motor tract, after the injection of caffeine into the circulation, caused violent muscular contractions, the same as before the injection. Its action on the brain is the same as that of theine, causing a local dilatation of the arteries supplying the brain, and therefore a hyperemia. The respiration center stimulated by caffeine quickens respiration, a most undesirable phenomenon in the growing child. Respiration becomes superficial and shallow, there is an increased amount of tidal air, and a consequent diminution of the exhalation of CO_2. As regards heat-production and tissue metamorphosis the investigations of E. D. Reichert are of great interest. He concludes that caffeine increases heat production, and as a corollary increases destructive tissue metamorphosis, and therefore coffee is injurious to health, especially when taken daily at frequent intervals. He also states that the assumed ability of coffee to replace food or to increase the power for work without corresponding tissue destruction is entirely deceptive, and the conditions produced by it are comparable to those occasionally observed in the insane, in hysteria, or in fright, when the individual may be capable of performing prodigious feats of strength and endurance, but nevertheless at the direct expense of his tissues.

As a causative factor in nervous disorders we can say that its rôle is that of a stimulant or depressant. It causes such disorders of the nervous system as

insomnia and restlessness, fullness and heaviness of the head; disturbances of special senses, as flashes of light before the eyes and ringing in the ears; frequency, irregularity, and intermittence of the heart's action, and muscular tremor.

When we come to consider tea as an etiological factor in backward children, it must be borne in mind that I allude to a strong decoction of tea, the form usually drank by those who habitually partake of the beverage. In the form of weak infusions drawn off from the leaves, I believe tea is harmless. Very little, if any, of the alkaloid or the tannin is dissolved, and its action is purely that of boiled water. The chief constituents of tea that exert a harmful effect on the system are theine, tannic acid, some volatile oil, and some less soluble ingredients. Its action on salivary and gastric digestion and upon the tubules of the kidneys is due to the large amount of tannic acid, upon the nervous system, and through that upon the muscles, to the alkaloid theine.

Dr. McKechnie reports some experiments to determine the influence of tea upon the digestion. He carried out these experiments by means of test tubes and of a gastric fistula formed in a monkey's stomach and found that tea infusion retards digestion. He is of the opinion that this is due not to the tannic acid alone, but also to some less soluble extractive matters. T. Lauder Brunton declares that the tannin in tea interferes very considerably with the digestion of fresh meat, but not with that of dried meat, such as ham or tongue. According to Roberts, tea has an intensely inhibitory effect, on account of the large amount of tannin, on the salivary digestion.

That tea prevents sleep is an experience with which every tea drinker has met. It quickens the intellect both in thought and imagination. As a result of the overstimulation a period of depression follows. In a report upon insanity in Ireland, in 1894, attention is called to the immoderate use of tea as a cause of mental diseases among the poorer classes. "While the moderate use of properly prepared tea," the report states, "is regarded as innocuous and even beneficial in its action on the nervous system, its ill effects, when decocted or overinfused, on persons who make it their staple article of diet, are dwelt on by almost all the resident medical superintendents in their several reports. Undoubtedly, the method of preparation adopted, and the excessive use of this article of diet, now so general among the poorer population, tend to the production of dyspepsia, which in its turn leads to states of mental depression highly favorable to the production of various forms of neurotic disturbances. Incidentally I want to mention that the report also states that the excessive use of tobacco, especially among the young, is thought to contribute in a minor degree to swell the statistics of mental failure. Dr. W. P. Spratling, in speaking of a case of multiple neuritis, mentions the significant fact that in Japan and India multiple neuritis is endemic, because of the habitual use of strong tea decoctions.

Dr. Thomas J. Mays, in contrasting the physiological action of caffeine and theine, states that his experiments made on frogs lead him to the following conclusions: (1) Theine produces spontaneous spasms and convulsions while caffeine does not. (2) Theine impairs the nasal reflex in the poisoning process, while caffeine does not, if at all, until the very last stage. Dr. Mays also claims that theine is a powerful local anesthetic. Thus we see that all the phenomena observed by Dr. Mays that were induced by theine, including spasms, convulsions, abolition of nasal reflex, and anesthesia, were purely of nervous origin.

With regard to its action on the structure of the kidney, Bartels states that tea acts sometimes as a diuretic due partly to its stimulant action on the heart and the rise of blood pressure, and partly to its stimulant action on the cells of the urinary tubules. As to its effects upon the urinary excretion, the following facts are given by Dr. W. J. Morton of New York. He made experiments on himself covering seven days: (1) A decided increase in the sulphuric and phosphoric acids and a moderate increase in the uric acid, while NaCl remained stationary. (2) A steady daily decline in the amount of urine excreted, on an average of 2 oz daily. (3) A large daily decline in the amount of urea excreted, on an average of 24 gr. per day. The most marked decline was that on the first day of 95 grains, when he suffered for twelve hours from extreme toxic effects of tea.

These results seem to point to nerve depression and a decrease of normal metabolism.

To sum up, then, tea in moderate doses is a stimulant to the nervous system, and in excess a depressant to the functional action of the nerve cells of the cerebrum, medulla, spinal, and vasomotor systems; and the nervous disorders produced by its use are such as are due to overstimulation and depression.

With such knowledge of the poisonous action of these drugs and from a study of the statistics as well as of the results obtained by my own investigations, I do not hesitate to say that the use of alcohol, tobacco, and coffee, or tea is an immediately exciting cause of backwardness in children.

A CASE OF EXTENSIVE LEUCOPLAKIA BEGINNING IN CHILDHOOD, ACCOMPANIED IN THE EARLY STAGES BY FOLLICULAR KERATOSIS OF THE SKIN, AND FOLLOWED BY CARCINOMA OF THE TONGUE.*

By M. B. HARTZELL, M.D.,
PHILADELPHIA.
ASSOCIATE IN DERMATOLOGY IN THE UNIVERSITY OF [illegible]; DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL.

While, as a rule leucoplakia must be regarded as a strictly local affection due to some locally acting cause, yet, in exceptional cases, it seems probable that it is but the local expression of a widespread tendency on the part of the epithelium to increased cornification resulting from some constitutional fault, congenital or acquired. In the following case an extensive buccal leucoplakia was apparently only a part of a widespread disturbance of the process of cornification, since the skin as well as the buccal mucous membrane was affected.

Miss X., at that time a girl eleven years old, was brought to me in December, 1891, on account of an affection of the skin which consisted of irregularly shaped, variously sized patches of dirty-gray spines situated upon the sides of the neck, and hemp-seed sized, flat, slightly elevated, scaly lesions scattered over the back. The spines upon the neck projected considerably above the surface of the skin, giving it a grater-like feel, and were evidently situated in the dilated mouths of the sebaceous gland ducts from which they could readily be extracted with forceps. The exact nature of the lesions upon the back was somewhat less apparent, but they were regarded as also keratosic. Unfortunately the one excised for microscopic ex-

*Read before the College of Physicians of Philadelphia, December 5, 1906.

amination was lost before the examination was completed. In addition to the cutaneous disease the entire mucous membrane of the lips, tongue, and cheeks was a bluish white, looking as if painted over with a strong solution of nitrate of silver. The disease of the skin, which was slowly spreading to new regions, had lasted eighteen months; the duration of the leucoplakia was somewhat uncertain, but it had lasted for a considerable time. After local treatment, extending over a period of ten months, which consisted chiefly in the application of fairly strong ointments of salicylic acid and pyrogallol, the latter being used only on the back, the skin affection disappeared; but the leucoplakia, for which mouth washes of various kinds had been prescribed, changed but little if at all. With the disappearance of the eruption upon the skin the patient was seen infrequently and only at long intervals, and the treatment of the disease of the mouth was soon practically abandoned, as it caused little or no annoyance. In February, 1906, she again came under observation, complaining of some soreness of the tongue and of a lump upon the side of it. Inspection revealed extensive and marked disease: the entire surface of the tongue was a yellowish white, with here and there irregular areas of superficial ulceration, and a small wart-like nodule upon the right side posteriorly. A diagnosis of epithelioma having been made, the patient was referred to a well-known surgeon, who, agreeing in this diagnosis, advised the removal of half the tongue, which was done a few weeks later. Unfortunately, after doing well for twenty-four hours, she died suddenly and most unexpectedly from what was supposed to have been pulmonary embolism, but as no autopsy was performed the cause of death must remain somewhat uncertain.

Microscopical examination of the nodule on the side of the tongue fully confirmed the clinical diagnosis of epithelioma. Long, branching, and anastomosing processes of squamous epithelium extended from the epidermis deeply into the corium, and here and there were rounded and oval masses of epithelial cells containing numerous pearly bodies, the whole presenting a characteristic picture. Other portions of the tongue presented interesting microscopical changes. The entire epidermis showed pathological alterations: in certain areas there was a marked increase in its corneous layer, while the rete mucosum was everywhere thicker than normal. Here and there the interpapiliary prolongations of this latter layer were greatly enlarged in all directions, extending an unusual distance downward into the corium, representing, probably, a very early stage in the transformation of the morbid process into carcinoma. Immediately beneath the epidermis there was an abundant cellular infiltrate made up, for the most part, of polynuclear leucocytes, but also containing many plasma cells and an unusual number of small "mastzellen." This cellular infiltrate was most marked where the alteration of the epidermis was greatest, and was present to a greater or less degree in all the sections examined; indeed, the entire tongue showed evidences of an extensive glossitis of moderate severity.

Apart from the unusual association of keratosis of the skin and mucous membranes the case presents other features of more than common interest. The early age at which the leucoplakia began is most unusual. Mr. Butlin, in his well-known treatise on diseases of the tongue, states that this affection is practically unknown before the age of twenty, and is very rare in women. As already noted, my patient was of the female sex, and was only eleven years old when first seen, and it is quite certain that the leucoplakia had already existed for a considerable time. The occurrence of carcinoma of the tongue in an individual so young (26 years old) is also decidedly rare. Of eighty patients with cancer of the tongue observed by Mr. Butlin, but two were under thirty years of age.

Cases of the kind just reported are rare in literature, but it is not likely that the number of published cases represents, even approximately, the frequency with which leucoplakia is associated with keratosis of the skin, since, owing to the absence of annoying subjective symptoms, mild degrees of the latter readily escape the notice of both patient and physician. Morrow, some years ago (*Journal of Cutaneous and Venereal Diseases,* 1886), reported the case of a sailor, 31 years old, in whom, along with a very extensive follicular keratosis, the entire follicular apparatus of the skin being involved, there was a marked leucoplakia of the tongue with fissuring, the disease having lasted five years.

While this peculiar form of keratosis is observed most frequently in the mouth, it is not limited to this region, but may occur upon other mucous membranes adjoining the skin, such as the vulvovaginal, the anorectal, and especially the balanopreputial, presenting the same appearances found in the buccal and lingual mucous membranes and pursuing the same course.

The proportion of cases in which carcinoma follows leucoplakia is large. In the series of eighty cases of cancer of the tongue already referred to, Mr. Butlin found that a more or less marked leucoplakia had preceded the appearance of the cancer in 20 per cent., and this author believes that the frequency of this sequel is under- rather than overestimated.

Owing to the frequency with which it is followed by malignant disease more definite and exact knowledge of its etiology than we possess at present is greatly to be desired. Smoking and syphilis are the etiological factors to which it is most commonly attributed, but it seems to me very doubtful whether any considerable number of cases arise from these causes; it is much more likely that any frequently repeated or long-continued irritation, joined with a special tendency on the part of the epithelium to hyperkeratosis, may produce it. That it is, in the beginning at least, an inflammatory affection is quite evident from a study of its histopathology, but it is equally evident that the inflammation must possess some special characters since ordinary inflammatory processes do not give rise to keratosis and carcinoma.

Leucoplakia is notoriously rebellious to treatment, and few local applications cause any perceptible improvement. For this reason it seems to me worth while to call attention to two remedies which have been of real service in my hands in the past year or two. These two remedies are weak ointments of salicylic acid, 3 to 5 grains to the ounce, applied several times a day, and the *x*-ray, the latter having proved especially beneficial in two cases. In a long-standing and very marked case affecting the mucous membrane of the lower lip, in which there were several small, thick, horny patches and superficial ulceration, the careful use of the *x*-ray was followed speedily by a complete cure. I feel, however, in recommending this agent, I should urge the utmost care in its use since the mucous membranes are extremely susceptible to its action, and too long exposures or too frequent repetition will surely do harm. The duration of the exposures should rarely exceed three minutes, and they should not be repeated oftener than every five days.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 9, 1907.

A PROPOSED ORGANIZATION OF ARMY SURGEONS.

IT is reported on good authority that there is no prospect of the passage of the bill for increasing the efficiency of the Medical Department of the Army, which is again to be sacrificed in favor of some other branch of the service. In the Spanish war the Medical Department was hampered until the public became frantic over the fever camps. In 1901, it was sacrificed to lessen opposition to the increase of the Army. In 1906, Speaker Cannon decided that only one military bill should pass, and the preference was given to the ordnance officers, and now the artillery is to be increased and the sanitary service again sacrificed. Congress seems to feel the weight of public opinion, which is naturally and properly against a large standing army. Increase of the force is deemed bad politics, and all changes towards greater efficiency must be carefully considered and grudgingly granted. Nevertheless, it seems remarkable that changes the least demanded by public opinion should be authorized, but that one for which there is the greatest clamor should be refused. The evidence of the urgent need of a better Medical Department is so great and overwhelming, it is amazing that Congress ignores it.

The cause of the lack of influence of the medical profession, and of the military part of it in particular, should be discovered. It has been suggested that the army surgeons are weak as a class because they have no organization. All their efforts are individual affairs, and lack the strength of concerted union. Their duties scatter them in all parts of the country, and now indeed of the world, they rarely see each other, there is no opportunity to organize, and they have made no advance in cooperation since the army was first organized.

There seems to be some truth in this suggestion. The cavalry and infantry officers are also scattered abroad, but each class is organized in associations for professional advancement. The military surgeons of the National Guard created an association which has taken in the Army, Navy, and Marine-Hospital services, but it is not exclusively interested in the Army Medical Department, and its members are mostly civil practitioners only temporarily attached to the local State militia as a side issue, and not as a profession. It does seem as though there were urgent need for the Army surgeons to organize for their own professional advancement, like all other specialists the world over. Indeed it would appear to be a duty. Congressmen are overwhelmed by private letters on thousands of subjects, and individual appeals to them are wasted effort. They really demand to know what an organization wants, and not what its individual members may suggest. Legislation is an impersonal and not a personal affair. The Army surgeons, then, should get together and work *en masse* for that increased efficiency which the good of the Army demands, and the absence of which was so deplorable in 1898. The public really look to the surgeons themselves to do this work, for no one will do it for them. Too much selfishness is always injurious in the long run, while a little self-sacrifice for the common good is often more beneficial to the individual himself. There is profound silence from most of the medical officers, so that we find it difficult at times to discover what are their wants, and what they think the Army needs. Congress wants the information, and so does the public. Organization would accomplish the purpose of inducing the surgeons to work in union and harmony, for the common good, and we see no reason why it should not be effected.

THE DANGERS OF GASTROENTEROSTOMY.

GASTROENTEROSTOMY has been favored to such an extent for the relief of a great variety of gastric conditions, that in the intense desire for its execution the conservative indications against such a procedure may only too often be forgotten. It is a matter of experience that the interference with the physiology of digestion which this operation entails is not well tolerated. The motor functions of the stomach are also disturbed by the procedure, for the churning power of this organ not only guarantees a thorough mixing of the food with the digestive fluids, but, as has been shown by experiment, the coarser particles of food are constantly being thrown back from the pylorus to the fundus and only the finely divided foods allowed to pass through the former. Portis summarizes the disadvantages and dangers attendant upon gastroenterostomy in a recent article in the *Annals of Surgery* for December, 1906, and, judging from his conclusions, it would appear that our general conception of the procedure is in need of revision.

The functional disorders of the digestive tract already referred to, which occur after gastroenterostomy and may seriously interfere with nutrition, and also the severe diarrheas, are due, not only to the premature emptying of the stomach, but also to the failure of neutralization by the bile and pancreatic juice of these acid secretions. This is due to the absence in the duodenum of the hydrochloric acid, which stimulates the flow of both of these. Jejunal ulcer following gastroenterostomy, which frequently occurs, and often with a fatal termination, should lead us, the writer believes, to advise the operation in question only as a last resort. It has also been suggested as a relief in certain cases of chronic dyspepsia in neurasthenic individuals where the condition is mainly due to imperfect mastication. Portis finds from a careful study of the reported results that here, as well as in the so-called atonic dilatation of the stomach and in gastroptosis, no benefit is derived from gastroenterostomy. In acute

ulcer of the stomach the operation is likewise not indicated unless perforation is imminent or has occurred, and in chronic ulcer only when repeated small hemorrhages menace life or there are extensive adhesions and the symptoms persist after prolonged and thorough medical treatment. The writer thinks that gastroenterostomy should always be done when the natural evacuation of the stomach is impossible and pyloroplasty or gastroduodenostomy is not feasible. This would include those cases in which there is mechanical obstruction due to pyloric stenosis and malformations due to hourglass contractions or disabling perigastric adhesions. When the operation is done, however, it is best to close off the pyloric opening. Although these views may not be in accord with the tendency which has been manifest within recent years to treat digestive disorders in great variety by operative procedures, they are eminently conservative, and if they should serve as a check to indiscriminate operation this can only act as an incentive to a more careful selection of cases in which such a course of treatment would actually be of value.

THE INJECTION TREATMENT OF SCIATICA.

Since the method of subcutaneous injection was first brought out by Wood of Edinburgh in 1853 it has been largely employed in the treatment of neuralgic affections. Various fluids of a narcotic or irritating character were used and met with favor for a time, only to be superseded by others. Schleich's name is also closely associated with the successful treatment of neuralgic conditions by the injection of his specially devised cocaine solutions into the perineural tissues. Sciatica was treated in this manner with very good results by a number of clinicians, cocaine or its derivatives being used. The toxic action of the drug continued to keep it more or less in disfavor, however, and as the results of the injection were deemed by many to be due to entirely mechanical causes the experiment was made of using physiological salt solution in its place, and Umber reports nine out of a total of fourteen cases cured by this means.

Notwithstanding the good results and the simplicity of the technique, these infiltration methods have not been very much used in actual practice, so that any new series of clinical observations should prove of interest. Among the latest of these is a report by Grossmann in the *Wiener klinische Wochenschrift*, No. 42, 1906, on fifteen cases of sciatica treated by infiltrations of salt solution. By means of a long needle (8 cm.) from fifty to one hundred grams of solutions may be injected, the needle being introduced directly down to the nerve at a point midway between the tuberosity of the ischium and the greater trochanter. The patient experiences a severe pain and paresthesia of the lower extremity as soon as the nerve is reached. The good effects of the injections are said to have been immediate, so that patients who were practically crippled could walk away from the operating table without assistance. In no instance were any unpleasant sequelæ observed. The effects on the disease in general were unfortunately not equal to the mere anodyne action of the injection, and in the majority of the cases the pain returned, but in a lessened degree, so that a second injection was necessary. The use of adjuvant measures such as hot air baths and hot packs was followed by excellent results, eleven of the fifteen patients being cured and three improved. It is evident therefore that although perineural injections cannot be looked upon as an absolute cure for sciatica, they do in combination with physical methods, produce a favorable result in most cases. The anodyne action of the procedure should certainly commend it for the alleviation, if only temporary, of this most painful affection.

APPENDICITIS AND JAUNDICE.

The appearance of icterus during the course of an appendicitis or following an operation for the relief of the latter condition has probably been observed by most surgeons, yet we find but scant notice taken of this complication in the very voluminous literature on the subject of appendical disease. That the condition is not infrequent is shown by the statistics of Reichel (*Zeitschrift für Chirurgie*, Vol. 83, No. 1), who found that among 165 of his cases of appendicitis jaundice had been noted in 18, and of these 10 resulted fatally. These mortality figures seem to afford sufficient reason for us to look upon this complication as indicating a very unfavorable prognosis. The type of jaundice under consideration is neither catarrhal nor obstructive, but is an indication of a general septic infection, the origin of which must be sought for in the inflamed appendix or its mesentery. Of quite a number of patients operated upon during the interval, Reichel found jaundice occurring in only one, and here the wound had suppurated.

Icterus, as a complication of appendicitis, usually occurs within from thirty-six to sixty hours after the beginning of the attack, and unless it subsides in a short time is rapidly succeeded by a condition of restlessness accompanied by a rise in the pulse rate, but not of the temperature. Reichel compares the clinical picture to that which we find associated with acute iodoform poisoning. In most cases the patients became delirious, then deeply comatose, and death followed in twenty-four hours. The fatal issue can only be ascribed to a severe and virulent septic infection, and this may be unaccompanied by peritonitis. In such cases not even an early operation will avert the unfortunate outcome. Reichel claims that the liver becomes involved by the transmission of masses of bacteria or infectious thrombi through the medium of the portal circulation. It would seem wise, therefore, to restrict all handling of the affected organ during an operation as much as possible, and the writer even urges that after forty-eight hours operative interference be limited to the evacuation of any abscesses which may be present.

Pancreatic Digestion in Man.

Thanks to the ingenious methods introduced into the physiological laboratory by Pavlov and his pupils, the processes of digestion have now been pretty thoroughly investigated, at least in animals whose functions are supposed to have a good deal in com-

mon with those of man. Through the impetus that gastric surgery has received of late years it has become possible in not a few cases to obtain confirmation in man of observations originally made in animals, usually dogs, and for the most part it has been found that the discrepancies in the results obtained are not very great. This is true particularly of gastric digestion, for opportunities of studying the physiology of the pancreas in man have so far been very infrequent. Such a case has, however, come under the observation of Wohlgemuth (*Berliner klinische Wochenschrift*, January 14, 1907) and has afforded material for some interesting studies. The patient was a man who was struck in the abdomen by a wagon pole and suffered a tear of the liver and a rupture of the head of the pancreas. He recovered from the injury, but a pancreatic fistula remained, and Wohlgemuth's observations were made on the juice collected from the sinus. It was found that, as in dogs, alterations in the composition of the diet caused great variations in the amount of juice secreted; for example, when fats predominated such as cream or milk, the flow was almost completely checked, meat caused it to increase, while carbohydrates gave rise to a very profuse secretion. Pavlov found in dogs that the secretion produced in response to either one of the three varieties of food stuffs would be richest in the particular ferment, *i.e.* amylopsin, steapsin, or trypsin, required for its digestion; but apparently this automatic adaptation does not take place in man, for it was found that the juice following the ingestion of fats was richest in all three ferments, while that accompanying the digestion of carbohydrates was weakest in its enzyme content. On the other hand, the effect of hydrochloric acid in stimulating pancreatic secretion and of alkalies in inhibiting it was the same in man as it had already been found to be in the dog. These observations would appear to justify a number of practical deductions, but Wohlgemuth so far restricts himself to the one suggestion that in dealing with cases of pancreatic fistula the diet should be a strictly antidiabetic one, and that alkalies should be administered, as in this way the secretion of pancreatic juice would be reduced to a minimum.

The Renal Origin of Increased Blood Pressure.

It is a commonly accepted belief that a constant elevation of blood pressure which may be associated with a nephritis is due to an adenomatous hyperplasia of the suprarenals and a marked stimulation of the functions of these organs. Ambard, in a recent communication (*Semaine Médicale*, No. 31, 1906), denies this and claims that the condition is entirely renal in origin. Although he admits that in nephritis this condition of the suprarenals is often found, it may also be present, he believes, when no elevation of blood pressure exists. In order thoroughly to comprehend the matter it is necessary to distinguish carefully between transitory and constant hypertension. The former is found in tabes, lead colic, eclampsia, epilepsy, exophthalmic goiter, and other conditions. Here the kidney is unchanged in its anatomical structure, and the tension is due entirely to functional disturbances. When the increase in arterial tension is permanent it is invariably associated with renal disease and may be either "reducible" or "irreducible." The former is found in connection with acute and subacute forms of nephritis, whereas those conditions of increased tension which are found with atrophic nephritis and advanced sclerosis of the glomeruli are irreducible. Ambard shows that increased tension in nephritis is not entirely dependent directly upon the changes in the vessels, but is caused also by the mechanical disturbances which result in a reduced permeability of the organ. Of importance in this connection is the relation between blood pressure and chloride metabolism. An increase in the blood pressure is favored by the retention of the chlorides, a decrease by an increased excretion of the same. Diuretics, such as theobromine, produce their effect on the blood pressure by stimulating the excretion of the chlorides. As controverting the usual ideas on the subject, Ambard's paper is of considerable interest and importance.

Education of the Cough in Tuberculous Patients.

The nature of cough varies from a slight irritable hacking commonly called "hemming" to the paroxysmal attack which may end in retching and vomiting. There is also a wide variation in the phonetic quality of cough. A cough may be metallic, stridulous, barking, or aphonic. A cough may occasion pain or this exertion may be painless. Sometimes a cough is frequent and continuous; in other cases it occurs only at certain times. Sometimes a patient coughs only on rising in the morning; again exertion may bring on a paroxysm. Change of temperature is another etiological factor to be considered. In 1878, Stoerk published a pamphlet in Vienna in which he discussed the existence of certain "cough-spots"—the posterior wall of the trachea, the interarytenoid fold, the under surface of the vocal cords, and the bifurcation of the trachea. This investigator does not believe that cough is caused by the accumulation of mucus in the small bronchi, but he believes that it must first reach one of the above-mentioned points. He does not, in this pamphlet, explain the cause of cough by reflex irritation. In *La Presse Médicale*, January 9, 1907, Ch. Mantoux discusses the cough of tuberculous patients. A tuberculous patient is nearly always a cougher. Since the remarkable work of Dettweiler, a distinction has been made in the case of pulmonary patients between the useful cough and the harmful cough. The useful cough is the one which serves to expel mucus. It ought to be reduced to a minimum; sometimes a "hem" which may at times be scarcely perceptible is sufficient to bring the mucus into the buccal cavity. The useless cough is one which does not end in expectoration, and every useless cough is harmful. Coughing fatigues the patient; it disturbs his repose and often his sleep. In some cases digestion is upset. It fatigues the muscles of the thorax and of the abdomen; it may even distend the abdominal walls to such an extent that hernia develops. It congests the larynx and the trachea. It disturbs the lungs by sudden and repeated changes in pressure when it is most advisable to immobilize these organs. It is a matter of common knowledge that a patient is often able to control a cough to a great extent by the exertion of his will power. He takes especial pains to do this when he is in the company of others, but when he is by himself there is not the same restraint, and he gives way to useless coughing. In order to prevent this the suggestion is made that the patient be instructed to indicate on a sheet of paper the number of times he coughs. In many cases this works like a charm, for these records are to be given to the physician at every visit, and the pride of the patient is bestirred to give a good account of himself.

THE RECOGNITION BY CONGRESS OF DR. CARROLL'S SERVICES TO SCIENCE.

THE Senate Committee on Military Affairs has voted to support a bill authorizing the promotion of Lieut. James Carroll of the Army Medical Corps to be a Major, and all who believe that devoted service in the cause of science is deserving of recognition will hope to see the bill passed. Dr. Carroll enlisted as a private thirty-three years ago, and was soon promoted to be a sergeant. He served as hospital steward for fifteen years and then, having in the meantime studied medicine and received a degree, was appointed contract surgeon in 1898. He was one of the commission under Major Walter Reed appointed to study yellow fever in Cuba, and was the first to submit to the bite of an infected mosquito in order to test the theory of the transmission of the disease. The severe attack of yellow fever which followed was the first link in the chain of evidence confirming Finlay's theory, and this example inspired others to submit to like tests. In 1902 he was appointed first lieutenant and assistant surgeon, the age limit having been waived to permit him to appear for examination. In the normal course of events, had he entered the medical corps at the usual age, he would now have reached the rank of major, and it is in recognition of his high scientific attainments and notable achievements in experimental medicine that this Senate bill has been introduced to give him the rank which others in the service of his own age have reached but which, by means of his late entrance into the medical corps, he could not attain in regular course. The highest rank which he could hope to reach before coming to the age of compulsory retirement would be that of captain. The proposed legislation is exceptional, but the circumstances calling for it are exceptional, for though Dr. Carroll's years in the medical service have been comparatively few they have been crowded with work of a high order, and of inestimable value to medical science and to humanity. The bill should be passed, if only to show that republics are not ungrateful.

News of the Week.

Scholarships and Fellowships of the Rockefeller Institute for Medical Research.—This institute purposes to award for the year 1907-1908 a limited number of scholarships and fellowships for work to be carried on in the laboratories of the Institute in New York City, under the following conditions: The scholarships and fellowships will be granted to assist investigations in experimental pathology, bacteriology, medical zoology, physiology and pharmacology, and physiological and pathological chemistry. They are open to men and women who are properly qualified to undertake research work in any of the above mentioned subjects, and are granted for one year. The value of these scholarships and fellowships ranges from eight hundred to twelve hundred dollars each. It is expected that the holders will devote their entire time to research. Applications accompanied by proper credentials should be in the hands of Dr. L. Emmett Holt, 14 West Fifty-fifth street, Secretary of the Rockefeller Institute, not later than April 1, 1907. The announcement of the appointments is made about May 15. The term of service begins preferably on October 1, but, by special arrangement, may be begun at another time.

Cocaine Selling and Bottle Washing.—At its regular meeting last week the Board of Health added two sections to the sanitary code, the one prohibiting the sale of cocaine except upon a physician's prescription, and the other requiring the exercise of proper cleanliness in dealing with milk and cream containers. This clause reads that it shall be the duty of all persons having in their possession bottles, cans, or other receptacles containing milk or cream, which are used in the transportation and delivery of milk or cream, to clean or cause them to be cleaned immediately upon emptying; and no person shall use or cause to be used any such receptacles for any purpose whatsoever other than the holding of milk or cream, or receive or have in his possession any such receptacle so used or which is unclean or in which milk or cream has been allowed to stand until offensive. Offenders will be liable for misdemeanor. This regulation is aimed principally at the wholesale and retail milk dealers, though housewives also come under its provisions.

New York State Child Labor Law.—The Senate Judiciary Committee on January 30 decided to report favorably and without amendment the Anti-Child Labor bill introduced by Senator Page and drafted in accordance with recommendations in the governor's message. The bill makes it a misdemeanor to employ minors under sixteen years of age in factories for more than eight hours in each twenty-four, and stipulates that the hours of employment shall be between 8 in the morning and 5 in the evening. The presence of a minor in a factory would be considered presumptive evidence of a violation of the law.

New Health Department Dispensary.—Last Monday the Health Department opened its third tuberculosis clinic. The new dispensary is in the Bronx Health Department Building, at Third avenue and St. Paul's place, and will be open Monday, Wednesday, and Friday afternoons, from 2 to 4 o'clock. Later it will be opened on Tuesday, Thursday, and Saturday afternoons, and possibly in the evenings also. The other two dispensaries are at the Health Department building, Fifty-fifth street and Sixth avenue, and in Brooklyn. Only consumptives are treated in these clinics.

Anti-Noise Bill Passed.—The bill intended to suppress unnecessary whistling by steam vessels plying in harbors about large cities, which was introduced through the efforts of Mrs. I. L. Rice of this city, has passed the Senate and is ready for the President's signature. Supervising Inspector Harris issued an order last November providing for the correction of the abuse, but until the bill becomes a law he is without authority to enforce the order if a case should be carried into the courts. The particular waters referred to in Mr. Harris' order are Boston Harbor, west of Castle Island; Philadelphia Harbor, between the uppermost and lowest lines of ferries, and in New York Harbor, the East River, Harlem River, North River, Spuyten Duyvil Creek, and Buttermilk Channel.

Lectures for Cancer Homes.—Dr. James J. Walsh of this city will give his third series of Lenten lectures in aid of the two homes for destitute cancer patients, managed by The Servants of Relief for Incurable Cancer. The lectures will be held on Thursday mornings during Lent at Mendelssohn Hall and will have as their subject "Some Women Who Did." The two homes of the organization, one at 426 Cherry street, New York, and the other at

Hawthorne, N. Y., are entirely dependent on charity, as no pay patients are treated.

New Medical Inspectors Appointed.—Twenty new medical inspectors have been appointed by the Health Department. Eleven of these will be assigned to Brooklyn, five to Manhattan, two to the Bronx, and one each to Richmond and Queens. There are at present thirty-two inspectors in Brooklyn and fifty-seven in New York. With these additions it will be possible to make the examinations of school children more systematically, and especially to investigate the sicknesses of absentees. Last year over one thousand cases of unreported infectious diseases were discovered in this way.

To Test Hudson River Ice.—Five chemists and bacteriologists in the employ of the Merchants' Association of this city have been sent up the Hudson to examine samples of ice taken from the various fields along the river where ice harvesting is going on, with a view to determining the healthfulness of the supply.

Contagious Diseases in Chicago.—It is estimated that the total number of cases of contagious diseases, particularly diphtheria and scarlet fever, that have occurred in Chicago during the present epidemic is not far from 15,000. New cases of both diseases are still being reported in great numbers, though it appears that the morbidity is beginning to decrease, and the later cases are of a somewhat milder type than the earlier ones had been. In particular many instances of the aberrant form of scarlatina sometimes called Duke's disease have been observed. In an effort to restrict the dissemination of the disease the health authorities have requested the citizens to abandon for the time being social engagements, such as balls and parties, though the schools and Sunday schools are not interfered with. A movement is also on foot for the establishment of a new isolation hospital.

Poisonous Embalming Fluids.—Senator Breit of the Illinois Legislature recently introduced a bill for the purpose of prohibiting the use of arsenic and strychnine in embalming fluids. He has prepared two bills, one of which reads that no undertaker or other person shall embalm or inject into the dead body of any person any fluid or preparation of any kind before obtaining permission from the coroner when such body is the subject of coroner's inquest. The second bill provides that, "if any undertaker or other person embalms with, injects, or places on any dead human body any fluid or preparation of any kind which contains strychnine or arsenic, he shall be fined not exceeding $50 for each offense."

State Sanatorium for Tuberculosis in Illinois.—A bill recommended by Governor Deneen, and introduced by Mr. Glacken, of Cook County, asking for an appropriation of $150,000, for the establishment of a State sanatorium for tuberculosis, is expected to pass.

Bureaus to Prevent Suicide.—The officials of the St. Louis Salvation Army have announced their intention of forming a department for the purpose of discouraging suicide. The project is founded on a similar plan which has been put in execution in London by Gen. Booth, and which it is said has prevented much loss of life through self-destruction. The plan is to give practical and friendly advice to distressed persons. This advice will be given daily, free of charge, to all who need it. Letters will be individually treated. Absolute secrecy is to be maintained in all cases, and no inquiries are to be made.

Insanity in Connecticut.—The biennial report of the Connecticut Hospital for the Insane, just published, shows that there are now 2,487 patients in the institution, and that the annual increase of insane persons in the State is about 120.

Woman's Army Canteen Club.—This organization of Washington, D. C., is making active efforts to have the canteens reestablished at army posts and is now engaged in founding branch clubs throughout the country in order to popularize the movement. A delegation which recently called upon President Roosevelt received the assurances of his personal support in the work, with which he is thoroughly in sympathy.

Death Penalty Abolished in Kansas.—Kansas, which has never had a legal execution, will probably never have one in the future, as a bill was passed by the Legislature on January 29 abolishing capital punishment. No Kansas governor has ever signed a death warrant, and the prisoners condemned to capital punishment have been treated as life convicts.

Report of British Tuberculosis Commission.—The Royal Commission on Tuberculosis appointed some years ago has issued a second *ad interim* report confirming the conclusion reached in the first *ad interim* report to the effect that Koch was mistaken in alleging that bovine tuberculosis was not a menace to the human race. The commission has arrived at the conclusion that there can be no doubt that a certain number of cases of tuberculosis occurring in the human subject, especially children, are the direct result of the introduction into the human body of the bacillus of bovine tuberculosis. There is also no doubt that in a majority of these cases the bacillus is introduced through cow's milk. This opinion is founded on a very extensive series of observations and experiments, which are described in the report. The late Sir Michael Foster was chairman of the commission.

Meningitis in Great Britain.—Cerebrospinal meningitis, which has hitherto been rather rare in the British Isles, is very prevalent in Scotland and the North of Ireland. It appears to be epidemic in Glasgow, where 103 cases, with 47 deaths, occurred in January.

Cocaine in India.—The Bureau of Commerce and Labor has been informed that the Government of India has prohibited the bringing in of cocaine by means of the post, and has restricted its importation by any other means to cases in which it is imported by persons, or by their authorized agents, who have been especially permitted to import the drug by a local Government or administration. The Government has also empowered the postal officials to search for any cocaine in course of transmission by post, and to deliver all such to the nearest excise officer.

Famine in China.—The reports from China continue to show the danger of a widespread epidemic that is accompanying the famine. It is estimated that 10,000,000 people, living in an area of 40,000 square miles, are affected to a dangerous degree by the lack of food, clothing, medical supplies, and proper shelter. In the huge concentration camps formed by refugees from the stricken districts the sanitary conditions are as bad as possible, and the authorities are overwhelmed by the task confronting them. An outbreak of plague is reported from Niu-chwang, which, however, is not in the famine district.

A New University in Frankfort.—A recent issue of the *Lancet* notes the beginning of a movement to establish a university in that city. Rich citizens are said to have collected funds for the purpose, but since the creation of universities belongs exclusively to the State and not, as in America, to private initiative, the funds will be given to the Government if it approves of the objects of the contributors. Frankfort has for a long time possessed the nucleus of a medical faculty; the old Senckenberg Institute, founded by a wealthy citizen, contains a number of well-furnished chemical, physical, anatomical, and other laboratories; the Royal Institution for Experimental Therapy under the direction of Professor Ehrlich attracts every year a great many graduates from other parts of Germany and from abroad; the hospitals of Frankfort are of the first rank, and contain an immense amount of clinical material which has not hitherto been used for teaching purposes. The establishment of a university will therefore be easy, so far as the medical faculty is concerned. No new universities have been founded in Germany for about a century, except at Strasburg, where the old university existing previously to the French occupation was reestablished in 1872.

Maine Academy of Medicine and Science.—In view of the fact that there is a bill relating to medical expert testimony now pending in the State Legislature of Maine, the Maine Academy of Medicine and Science has decided to devote its next regular meeting on February 13 to medicolegal subjects, and Mr. Clark Bell of this city has accepted an invitation to deliver an address.

Springfield (Mass.) Academy of Medicine.—At a meeting of the leading physicians of western Massachusetts, held in Springfield on January 24, preliminary steps were taken toward the founding of the Springfield Academy of Medicine, a post-graduate institution for the teaching of medicine and its advancement generally on a cooperative basis. The officers elected are: *President*, Dr. J. A. Houston, Superintendent of the State Hospital for the Insane at Northampton; *First Vice-President*, Dr. R. H. Seelye; *Second Vice-President*, Dr. A. O. Squier; *Secretary*, Dr. W. R. Weiser; *Treasurer*, Dr. W. H. Van Allen. Articles of incorporation will be filed and a charter applied for under the laws of Massachusetts. It is also planned to erect a handsome academy building.

The American Society of Sanitary and Moral Prophylaxis.—The next annual meeting of this society will be held at the New York Academy of Medicine on Thursday, February 14, at 8:30 P.M. Papers will be read by Drs. Herman G. Klotz, James Pederson, A. D. Mewborn, Follen Cabot, Jr., and Frederick Holme Wiggin.

The Medical Society of the County of Kings.—At the annual meeting of this society, held January 16, 1907, the following officers were elected: *President*, Dr. Glenworth Reeve Butler; *Vice-President*, Dr. Onslow A. Gordon; *Secretary*, Dr. Henry G. Webster; *Treasurer*, Dr. John R. Stivers; *Associate Treasurer*, Dr. H. M. Mills; *Associate Secretary*, Dr. W. A. Jewett; *Directing Librarian*, Dr. James P. Warbasse.

Annual Meeting of the Chicago Medical Examiners' Association.—At the annual meeting of this association, held January 31, Dr. J. M. Patton was elected *President*, Dr. E. Eisenstaedt *Secretary*, and Dr. Ulysses Grimm *Treasurer*. The society adopted a resolution advocating the establishment of a National Department of Public Health.

Santa Barbara (Cal.) County Medical Society.—The officers for this society for the year 1907 are: *President*, Dr. C. S. Stoddard; *Vice-President*, Dr. E. A. Dial; *Secretary*, Dr. W. T. Barry; *Treasurer*, Dr. D. A. Conrad; *First Vice-President-at-Large*, Dr. W. A. Rowell, Goleta; *Second Vice-President-at-Large*, Dr. R. W. Brown, Santa Maria.

Muscatine County (Ia.) Medical Society.—The election of officers of this society for the ensuing year has resulted as follows: *President*, Dr. F. H. Little, Muscatine; *Vice-President*, Dr. C. B. Kimball, West Liberty; *Secretary-Treasurer*, Dr. T. F. Beveridge, Muscatine.

Nueces County (Texas) Medical Association.—Officers as follows were elected at the recent meeting of this society, held at Corpus Christi: *President*, Dr. Henry Redmond; *Vice-President*, Dr. W. E. Carruth; *Secretary and Treasurer*, Dr. C. H. Yeager.

Trumbull County (Ia.) Medical Association.—At the meeting recently held in Warren officers were elected as follows by this society: *President*, Dr. D. E. Hoover; *Vice-President*, Dr. T. O. Clingan; *Secretary and Treasurer*, Dr. F. K. Smith.

Aroostook (Me.) County Medical Society.—The medical societies of northern Aroostook and southern Aroostook have united in one organization—the Aroostook County Medical Society, which met at Houlton last week and elected officers as follows: *President*, Dr. A. D. Sawyer, Fort Fairfield; *Vice-President*, Dr. H. L. Putnam, Houlton; *Secretary*, Dr. F. H. Jackson, Houlton; *Treasurer*, Dr. W. E. Sincock, Caribou.

Iowa Clinical Surgical Society.—Under this name a new society has been formed in Des Moines, with the following officers: *President*, Dr. Pond, Dubuque; *Vice-President*, Dr. McCarthy, Des Moines; *Secretary and Treasurer*, Dr. Fairchild, Jr., Clinton. The State is divided into four districts, which will be in charge of the following counselors: Dr. Brockman, Ottumwa; Dr. Knott, Sioux City; Dr. Macrae, Jr., Council Bluffs; Dr. Hegebeck, Dubuque.

Sir Michael Foster, K.C.B., died on January 30, at the age of seventy-one years. At the time of his death he was Unionist member of Parliament from London University, his election dating from 1900. He held at various times the posts of professor of practical physiology at University College, London; prælector of physiology, Trinity College, Cambridge; president of the British Association; professor of physiology, Cambridge; and secretary of the Royal Society. He was joint editor of "Scientific Memoirs of Thomas Henry Huxley."

Prof. Dmitri Ivanovitch Mendeleef of St. Petersburg died on February 2 at the age of seventy-three years. He was for many years professor of chemistry in the University of St. Petersburg, and had made numerous discoveries in that branch of science. He was best known for his researches on the periodic law in relation to the elements, and by its means was able to predicate the existence and general properties of the three elements, gallium, scandium, and germanium, before they were discovered.

The Late Dr. William P. Brandegee.—The following minute has been adopted by the New York Otological Society: *Whereas*, During the past summer death suddenly called from us our friend

and fellow member, Dr. William P. Brandegee; and *whereas*, in his professional and private life he was known to us as an excellent example of all for which this society stands; then be it *Resolved*, That we place upon record the deep sense of sorrow which we feel at the loss of our colleague, and that we extend our sincere sympathy and condolence to the bereaved family. *Resolved*, That a copy of these resolutions be sent to them, and a copy be sent to the medical journals for publication. (Signed.) Arthur B. Duel, James F. McKernon, Joseph A. Kerefick.

Obituary Notes.—Dr. E. Elsner C. Guntiier of this city died on January 31 at the age of forty-two years after an illness of several months. He was born in this city and graduated from Harvard in 1889. He then entered the Harvard Medical School, after which he completed his professional education abroad.

Dr. George Douglass of Whitmire, S. C., died on January 22 at the age of fifty-six years. He was graduated in medicine in Baltimore in 1897 and had practised in Whitmire ever since.

Dr. Absalom W. Adair of Des Moines died suddenly of apoplexy on January 22 at the age of seventy-eight years. He was a pioneer physician of Jasper county, and had practised in the town of Kellogg until five years ago, when he removed to Des Moines.

Dr. B. F. Crummer of Omaha, Neb., died on January 24 at the age of fifty-nine years, as the result of an attack of paralysis beginning ten months ago. Dr. Crummer was born at Elizabeth, Ill., and received his medical education at the University of Ann Arbor and Bellevue Hospital Medical College in this city. He went to Omaha in 1888 and had practised there since that time.

Dr. Augustus V. L. Brokaw of St. Louis died on January 25 of a gastric affection at the age of forty-four years. He was born in St. Louis, his father, Dr. F. V. L. Brokaw, being the superintendent of the St. Louis City Hospital. He was graduated in medicine from the medical department of Washington University in 1883 and then spent some years abroad. He held several teaching positions at the time of his death and was well known as a railway surgeon.

Dr. Elliott H. Woolsey of Oakland, Cal., died on January 21 of pneumonia, after a brief illness. Dr. Woolsey was born near Rochester, N. Y., in 1843 and was educated at Hamilton College. He served as a surgeon in the regular army during the Civil War and shortly after its close he went to California, beginning to practise in Oroville. In 1873 he removed to Oakland and soon became prominent in medical circles. At different times he was president of the State Medical Association, Health Officer of Oakland, and member of the Oakland Board of Health, and for a number of years he conducted a free clinic for the poor. He retired from practice eight years ago, since when he had spent most of his time in travel.

Dr. J. Henry McNeel of Fond du Lac, Wis., died on January 23 of apoplexy. He was born in Essex county, N. Y., in 1838, and in 1854 his family emigrated to Wisconsin. He received his medical degree from Rush Medical College in 1863 and began practice at Greenbush, Sheboygan county, where he remained until 1872, when he removed to Fond du Lac. He was for several years a member of the State Board of Health and had also served as a member of the State Legislature.

Dr. Josiah P. Sugg of Tarboro, N. C., died on January 24 at the age of sixty-six years. Dr. Sugg was a native of North Carolina and received his medical education in the College of Physicians and Surgeons of this city.

Dr. Halsey B. Jenks of Ypsilanti, Mich., died on January 22 at the age of sixty-four years. He was a veteran of the Civil War, having served in the Twentieth Michigan Infantry, and was graduated from the University of Michigan Medical School in 1870.

Dr. Thomas F. Mayham of Fond du Lac, Wis., died suddenly on January 21 at the age of seventy-seven years. He was born in Blenheim, N. Y., but removed to Fond du Lac in 1854. After serving for some years as a school superintendent, he was graduated from the medical department of the University of Ann Arbor in 1859. He was elected Mayor of Fond du Lac in 1882 and held the office during several terms.

Dr. Wm. E. Ard of Westchester died on January 24, 1907, aged forty years. He was a graduate of the University of Maryland, was formerly house surgeon on the staff of the Woman's Hospital in this city, and attending surgeon to the City Hospital in Binghamton. He was practising in Westchester, New York City, until a few months before his death, when failing health compelled him to give up his work.

Dr. William Clawson Lott died at Philadelphia on January 22 at the age of forty-seven years. He was graduated from Brown University in the year 1882 and from the medical department of the University of Pennsylvania in the class of 1885. His earliest ancestor in America settled in New England in 1635 and he came of distinguished Revolutionary stock. He was a member of the First Troop, Philadelphia Cavalry, in which he served as quartermaster sergeant in Porto Rico during the Spanish-American War.

Dr. Wm. H. H. Miller died at Williamsport, Pa., on February 2 at the age of eighty-two years. He was graduated from the Pennsylvania Medical College in the class of 1849.

Correspondence.

THE NATURE OF JENSEN'S MOUSE TUMOR.

To the Editor of the Medical Record:

Sir:—My attention has just been directed to a letter in your issue of January 5, from Dr. Beard of Edinburgh. I welcome criticism even when it is adverse, but I deprecate gross misrepresentation such as enters largely into his communication.

Dr. Beard's special point against me is that I have not adduced my scientific reasons for denying the cancerous nature of Jensen's mouse tumor, but have, instead, endeavored to get the matter decided by an unscientific *ipse dixit*. Considering that the publication he refers to is a closely reasoned argument in support of my thesis, in which every special fact bearing on the subject is duly set forth and appraised, I must repudiate his suggestion as being neither reasonable nor fair.

The great mistake of those who have so prematurely identified "Jensen's tumor" with cancer is that, in making their diagnosis, they have placed far too much reliance on histological appearances—the fallaciousness of which has so often been demonstrated in recent times—and far too little on the *ensemble* of the indications available for diagnostic purposes. Dr. Beard's so-called "chemical test" for cancer belongs to the same order of fallacious experience; for chemical analysis has hitherto failed to reveal the presence of any specific cancer substance. The claims of Petry, Bergell, Blumenthal, *et al*, to have discovered a special cancer ferment, have very little basis in ascertained fact, but are rather the outcome of apriori considerations, which differ but little from Rokitansky's "kakoplastic albumin," and other kindred speculations, long since forgotten. The tissues of malignant tumors, like the normal

tumors probably teem with enzymes, but there is no proof that their specific qualities or quantities are in any way proportional to malignancy. As Buxton has judiciously remarked: "It has been shown that a number of enzymes are commonly present in cancerous tumors, but their amount and kind are independent of the character or malignancy of the growth, and are very similar to those found in the normal tissues of the same part." In short, it is evident that until we know more about the enzymes of normal tissues it is impossible to arrive at any definite conclusion as to the special significance of the enzymes of cancerous tumors. It quite accords with this, that cancerous tumors originate fairly often in the pancreas, and that their constituent cells secrete trypsin—"the killer" of cancer, according to Dr. Beard—as the important researches of Waring and others have clearly proved. In the light of the long-continued and oft-repeated failure of morphology and chemistry to reveal the presence of any specific cancer substance, we shall probably not be far wrong in concluding that there are no specific cancer substances, other than such as are concerned in determining the specificity of the various physiological tissue elements.

Now what are the plain facts in respect to which "Jensen's tumor" differs *in toto* from cancer or any form of human malignant tumor? They are briefly these: The disease is highly contagious; thus, when infected animals are introduced into cages with healthy animals the latter take the malady, as if by local contagion; and sometimes the proportion thus infected is so considerable as to constitute veritable epidemics. Nothing like this occurs with human cancer—at least, not outside the Munchausen sphere—but in the contagious venereal malady of dogs analogous conditions are commonly met with. "Jensen's tumor" is readily transmissible by implantation to other mice, the proportion of successful experiments often being as high as 30 per cent. No such property is ever manifested by human cancer; but, with the contagious venereal pseudoplasms of dogs similar conditions obtain. A considerable proportion of white mice are immune to the contagion of this disease, whether in its spontaneous or experimentally determined form, and sometimes whole families manifest the peculiarity. The same phenomena have often been noted in the contagious malady of dogs. Moreover, "Jensen's tumor" fairly often (over 20 per cent. —Clowes) undergoes spontaneous cure; and the cured animals are then immune to further contagion, and give only negative results when inoculated, as Gaylord has specially pointed out. With human malignant tumors no such spontaneous curability has ever been scientifically demonstrated, although sometimes alleged; but, in the several pseudoplasms of dogs, this phenomenon is of common occurrence. "Jensen's tumor" is circumscribed and easily enucleable, the tissues of the host forming no part of it; moreover, the latter do not acquire cancerous properties, nor do they become interpenetrated by injurious processes of the neoplasm; and besides this, "Jensen's tumor" causes no cachexia. Finally, according to Apolant and Ehrlich, "Jensen's tumor" in the course of experimental transmission often changes its type—from the epithelial to the sarcomatous, etc., and Morau found, under similar circumstances, that its physiological type also changed, with corresponding alteration in its power of inoculability.

In all of these vitally important respects, which, taken together, are crucial for diagnostic purposes, "Jensen's tumor," whatever its real nature may eventually turn out to be, is totally unlike any form of human malignant tumor.

W. Roger Williams.

Clifton, Bristol, England.

UNNECESSARY OPERATIONS THE OPPROBRIUM OF MODERN SURGERY.

To the Editor of the Medical Record:

Sir:—It cannot be denied that at the present day many operations are performed that are not only unnecessary but unjustifiable. This is especially true of abdominal and pelvic surgery. Time was when ovaries were removed by the peck for all sorts of nervous disturbances, which had no more to do with the condition of the ovaries than with the change of the moon. This was the era of Battey's so-called "normal ovariotomy," than which no greater outrage could be perpetrated upon a confiding woman. To-day it is not fashionable to remove the ovaries for an attack in which the globus hystericus is the most prominent symptom, but those organs are still subjected to certain operative procedures for pathological conditions which exist only in the mind of the operator. At times the ovary is removed for what the operator is pleased to dignify by the term of "ovarian cyst." This cyst is sometimes no larger than a cherry, and very often much smaller. At times the ovary is not removed, but the cyst is punctured with knife or cautery, and the fallopian tube, which he claims is the seat of salpingitis, but which may be perfectly normal, is resected. What justification is there for opening a woman's abdomen for such conditions? The operator may justify himself by saying that the woman suffered from pelvic pain which justified the operation. Now, every experienced gynecologist knows that this is not true; such conditions do not give rise to pain. If the woman really suffers pain she is probably a neurotic subject, whose pains and aches are due to anemia and general malnutrition. If she did not have pain in her pelvis she would have it somewhere else. Anstie has truly said "neuralgia is the cry of the nerves for healthy blood," and such patients require iron, fresh air, sunshine, and good food—not a mutilating operation.

The uterine adnexæ are not the only organs subject to atrocious assault, the uterus itself comes in for more than its fair share. To say nothing about the injury so often inflicted on it by the ignorant, through bungling attempts at dilatation and curettage, or malad[illegible] it trachelorrhaphy, the organ is often extirpated for no apparent reason, except the undying fondness of some men for notoriety or money. The uterus is often removed for a small myoma the size of a walnut. The writer saw two such cases during the past month. In one case abdominal hysterectomy was done by a prominent New York surgeon; in the other an inexperienced man performed a vaginal hysterectomy, which was attended by so much hemorrhage that he opened the abdomen in the hope of controlling it. In this he was not successful; more or less bleeding continued until the death of the patient about two days later. At the December meeting of the Obstetrical and Gynecological Section of the New York Academy of Medicine, Dr. Henry C. Coe protested against the performance of hysterectomy for insignificant benign growths, and the writer, in indorsing Dr. Coe's protest, stated that in his opinion such operations should be looked upon as pure surgical quackery. The overzealous gynecologist seems to be constantly in search of an opportunity to extirpate the uterus. If a woman has a large subinvoluted uterus with catarrhal endometritis attended by profuse menstruation, he scrapes the uterus and sends some of the scrapings to a personal friend—a *soi-disant* microscopist, who would not know a cancer cell from a load of hay. His friend, the "microscopist," having been told what the would-be operator "fears," proceeds to find "suspicious-looking cells." That is enough—out comes that uterus. Again, a woman has a badly lacerated cervix with ectropion and erosion. The cervix has certainly an angry look, but the experienced man knows that it is not cancerous. He has operated on scores, yea, perhaps hundreds, of similar cases by Emmet's method, and they have been permanently cured. But our enthusiastic confrère is ultra scientific. He is not willing to trust to his naked eye, or anybody else's naked eye; so he chips off a piece of the cervix and sends it to the same microscopist, being careful to tell him what he himself thinks. The microscopist is either again "suspicious" or "in doubt," and, as Cavendish says in regard to whist, "when in doubt play trumps," our friend plays trumps, and out comes that uterus also. Far be it from the writer to disparage the well-trained, intelligent, honest microscopist, whose assistance is invaluable in many doubtful cases. He makes reference to those who, without proper qualification, pose as experts, and whose opinions are often used by those who are overanxious to operate as a make-weight in overcoming the objections of patients or of the family physician, to operations which should never be performed. In a paper entitled "A Plea for Early Operation in Cancer of the Womb," the writer has denounced the criminal neglect and procrastination which allows a woman with cancer of the uterus to drift into an incurable state before she is referred to an operative gynecologist, and he sincerely hopes that nothing contained in this communication will detract from the force of what he then said. Every available means at our command should be brought to bear that may enable us to diagnose cancer in its incipiency.

It is one thing to make an honest search for the truth in the interests of the patient and quite another thing to play the charlatan, while pretending to base one's practice upon scientific accuracy. Next to the uterus and adnexæ, the appendix vermiformis and kidney are the most abused organs. With some practitioners every belly ache is called appendicitis, and an operation for the removal of a normal appendix follows forthwith. The writer has seen the appendix removed in a number of cases in which it was absolutely normal, and within the past five years he has been consulted by many women who had been told that they should submit to an operation for what was said to be appendicitis, but the subsequent history showed that no operation was necessary in most of the cases; and in those in which abdominal section was necessary it was found that the appendix had nothing to do with the symptoms

complained of. In times gone by, when a physician was too indolent or too ignorant to make a diagnosis, he labeled the disease "malaria," and everybody was satisfied. Now the so-called surgeon calls everything appendicitis, and cuts out the appendix, with equally gratifying results. The furor for unnecessary operations has spread to the laity, and the cheerfulness with which the would-be fashionable man parts with his appendix is only equaled by the *abandon* with which the modern woman submits to the evisceration of her pelvis by her pet gynecologist. Practising fantastic operations on the kidney keeps some men in the profession busy. A poor, thin, neurotic woman, whose circumrenal fat has been absorbed, leaving the kidney anchored only by its moorings, consults one of these men. With wonderful sagacity he diagnoses "floating kidney" and at once performs nephrorrhaphy. If from rest in bed and general improvement in health therefrom a layer of fat is deposited around the kidney the woman is cured, and the doctor gives the credit to the operation.

If the patient does not gain flesh after the operation, in a few months the kidney "floats" again as badly as ever. But the operator may remain ignorant of the fact, for the patient may consult somebody with common sense enough to put her in bed, feed her generously, remove all sources of worry, and thus put her in the way of gaining flesh, and after a time the kidney stays where it belongs. Splitting the capsule has been advised and practised as a panacea in Bright's disease. The writer has no knowledge of any authentic case in which a cure has been effected, but he knows of one case reported as a cure, although the patient died a short time after the operation, and the kidneys are in pickle in a jar which is the property of a well-known pathologist. Prostatectomy seems to be the latest fad, and the man of sixty who is still carrying his prostate where nature intended that he should, is looked down upon by his contemporaries who have yielded theirs as a contribution to extend the popularity of this surgical innovation. Let us hope that the interest shown in the prostate may result in giving a much needed rest to the appendix and the kidney.

From long experience the writer is fully aware of the difficulties and responsibilities involved in the diagnosis and treatment of serious abdominal and pelvic lesions, and is ever ready to deal charitably with the errors of judgment of a professional brother. We all make mistakes—we all are liable to sins of omission and sins of commission; but there is a vast difference between the honest mistakes of the well-trained, intelligent surgeon, who looks upon every case with an eye single to the good of the patient, and the stupid blunders of the inexperienced or meddlesome operator, whose ignorance of pathology and of the natural history of disease causes him to see in every case an indication for operation, and who is ever willing to sacrifice the good of the patient to his own love of self aggrandizement.

Paterson, N. J.

RECURRENT CORYZA IN CHILDREN.

To the Editor of the Medical Record:

Sir:—In your issue of January 5, 1907, there appears an abstract of my paper entitled "Rhinitis in Children, Including Recurrent Coryza, Due to Intestinal Autointoxication." In this article I am quoted as saying: "When this form occurs in children the urine invariably contains indican. The peculiar gastric and intestinal disturbance arises from overeating of meat. It should be prohibited in every form as soon as any evidence of the rhinitis appears. Saline cathartics should be given, sodium phosphate being administered in sufficient quantities to produce liquid stools, and the administration kept up until the urine contains indican." In the article referred to, I say:

"When the intestine contains stagnant fecal matter a general autointoxication results, frequently ending in rhinitis. . . . . These attacks last but two or three days. They recur, unless a general cleansing of the gastrointestinal tract, as often as once a month in some cases, is given. . . . . When recurrent rhinitis is seen in dyspeptic children then the urine invariably contains indican. . . . . Not only is the presence of indican an important aid in eliciting the etiological factor in this type of recurring rhinitis, but the presence of indican assumes a very important rôle in determining the proper therapeutical measures to be pursued. From what has just been said we can easily see that if indican exists, associated with stagnant feces (chronic constipation) then the treatment is one of distinct elimination."

From the above it will be seen that the diagnosis is strengthened by the presence of either large or small quantities of indican in the urine, and the stronger the blue reaction of indican the larger the amount present. Hence the point would be to keep up the eliminative treatment until the urine shows less and less, or only the normal trace of indican.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITALS AND THE COMPENSATION ACT—TROPICAL DISEASES—MUNICIPALITIES AND INFANTILE MORTALITY—ARMY AND NAVY AFFAIRS—MEDICAL OFFICERS OF HEALTH; PRESIDENTIAL ADDRESS—SIR C. DOYLE ON EDALJI'S CASE—PROPOSED BILL FOR THE KING'S HOSPITAL FUND.

London, January 18, 1907.

The friends of hospitals are concerned to know what will be the effect of the extension of the principle of compensation for injuries to whole classes of the population under the new Act. The King's speech at the Prorogation of Parliament put the enlarged scope of compensation as embracing "over six million persons not included under the benefits of preceding Acts." The added burden to our hospitals will be obvious on the slightest thought on the subject. Most of those entitled to compensation are likely to become patients at the hospitals. In minor cases the injured workman can get the best medical and surgical aid at the nearest hospital without cost, and this help tends to reduce to a minimum the period of his incapacitation. In graver injuries he will become an in-patient, and receive in addition free maintenance. But neither he nor the employer need give a penny to the hospital which has benefited both, nor can the amount received for compensation be attached for the expenses incurred by the hospital.

This hospital grievance has been felt more or less acutely ever since the compensation of workmen was rendered compulsory by law, and at intervals it has been made the basis of a claim that the great insurance companies should give pecuniary help to the hospitals, for these institutions enable the companies to reap large profits from the diminution of their risks through medical skill. This applies specially to those companies which do the largest business among the working classes. I do not mean to deny that insurance companies, or some of them, subscribe to hospitals, but I think no one can maintain that they afford adequate financial support considering the benefits they receive.

Another point is giving some concern to hospital managers and others. It seems as if the new Act will render the governing bodies of hospitals responsible for injuries occurring to "all persons in the regular employ" of these authorities. If so, it will be prudent for them to insure such persons, and this will be an additional burden on hospitals and an equal benefit to insurance companies. The outlook for the hospitals is not pleasant.

In the report of the Advisory Committee of the Tropical Diseases Research Fund for last year, the objects are said to be, on the one hand, provision of instruction for medical officers in the Colonies and Protectorates; on the other hand, the furtherance of research work. The first of these ends is said to have been in great measure attained by the provision of lectureships in entomology and parasitology, in helminthology and protozoology, at the Liverpool and London schools. Medical officers appointed to posts in the Crown Colonies or Protectorates are now required to take a three-months' course in one of these schools. It has lately been suggested that the course should be six months. The committee, however, think the expense and delay would be serious, and if any change be made it should be by enabling those medical officers who display exceptional promise to attend a more advanced course on the occasion of their first leave of absence in England. As to research, the Colonial Secretary, on consultation with expert advisers, sent a circular to the Governors of Colonies and Protectorates, suggesting that when they have an adequate staff, and can devote some funds, a sum might be voted for detailing one or more medical officers to study modern scientific research at the best known centers, and possibly afterwards to carry out further researches in the Colony before reverting to ordinary work. The committee express satisfaction that the appointment of a professor of protozoology at the London University has been followed by a similar step at Cambridge. They are considering a proposal to establish a post for investigation and instruction in pathological entomology in connection with the London University and Tropical School. The work done in the Tropical Schools is certainly most satisfactory, and the report seems to recognize this, especially in relation to prophylactic measures suggested as the result of their labors.

At the dinner of the African Society last week, Sir Patrick Manson was the guest of the evening, and in his

speech referred to the progress in the study of tropical diseases in the last eight or ten years, before which time quite half a dozen were lumped together as malaria. Sleeping sickness having crept into the Congo and devastated Uganda, now threatened the upper Nile, and might possibly reach India and tropical Asia, "a calamity to mankind too terrible to contemplate." He considered it of the utmost importance for immediate steps to be taken to guard against that as far as possible, and a hopeful sign was that people were beginning to learn the value of research on these diseases.

Some of the municipalities, including Glasgow, which calls itself the second city of the Empire, will seek powers in the coming session of Parliament to deal more effectually with infantile mortality and the decline in the birth-rate. Among the proposals made is one enacting that the father, or, in his absence someone in attendance on the mother, shall, within forty-eight hours of a birth, give notice to the medical officer of health, and shall be paid by the municipality one shilling for so doing, but fined twenty shillings for neglecting to do so. Public notice is to be given in the papers and by handbills, and medical practitioners and midwives are to be informed by registered letters. This proposal is not as a substitute for ordinary registration, but as an addition thereto. The time allowed for informing the Registrar would be too long for the purpose of this proposal, which is to enable the local authority to do more effectually what has been done in some places by volunteers, viz., to have poor mothers visited at once by ladies in order to assist them, instruct them when necessary on the feeding and management of the infant, and do all they can to secure it the best chance of survival during the first weeks of life—the most dangerous period. In connection with this subject, the London County Council, with its omnivorous propensities, could not be behindhand. It has, in fact, deposited a bill of ninety-two clauses extending its powers in various directions. One clause proposes that any Metropolitan Council may carry on milk depots and provide plants and laboratories for sterilizing or treating milk so as to make it suitable for infants under two years. But our Council does not stop here; it has a scheme for running a sort of restaurant in connection with its several lodging houses, selling "every description of food, solid or liquid," but the latter not intoxicating. This last proposal is being denounnced by many. It is very well, they say, to set up the milk depots, which seem successful, but that is no reason for opening shops to compete with rate-payers by means of rate-payers' money, and there is always a risk of loss, as the Council knows from its speculations in steamboats and other business failures. The electors may have something to say on these matters.

The amalgamation of the Army Medical Advisory Board and the Army Hospital and Sanitary Committee is now completed, and the War Minister announces that the reconstituted "Army Medical Service Advisory Board" is composed of the Director-General and Deputy-Director-General, Army Medical Department, as chairman and vice-chairman. Col. Bruce, F.R.S., is a member as "expert in Tropical Diseases," and Lieut.-Col. Melville, M.B., as "expert in Sanitation." Col. Moncrieff, C.I.E., Assistant Director of Fortifications, also has a seat. The civilian members are Sir F. Treves, Dr. Rose Bradford, Dr. Louis Parkes, Dr. Pembrey, and Sir C. A. Cameron. As a representative of the India office, Surgeon-General Branfoot is appointed, and the secretary is Lieut.-Col. Melville, M.B., the "expert in Sanitation."

The report on the Health of the Navy in 1905 is out this week. Compared with the averages of the last eight years, there are decreases in the ratios of cases, invalidings, and deaths, the death ratios being the lowest since 1856. The ratio for the year was 3.9 per 1,000, a decrease of 1.42 compared with the eight years. The daily average ratio of sickness was 30.31 per 1,000, which is a decrease of 1.04 compared with 1904.

The report of the Army Medical Department is also just published, but the statistics are not comparable with those of the Navy. There is a decrease in the admissions, mortality, and sick rates. The decrease in the admission rate is partly traced to the practice of treating cases in barracks, which under old rules would have been dealt with in hospital. The death rate for the year shows a decrease on the previous year, as well as on the average for decennium 1895-1904. It is also to be observed that the death rate is not that of sickness originating solely in the United Kingdom, but by that contracted while serving abroad, and here I have only referred to the statistics of the Army serving at home.

The new president of the Society of Medical Officers of Health is Dr. D. S. Davies, Medical Officer of Health for Bristol and lecturer on hygiene at the University. In his inaugural address he referred to the conception of disease prevention as a general formula having undergone great modification, and to the early notion on the discovery of pathogenic bacteria that they entered, permeated, and then passed out of the body like an army without stragglers. Had this been true, isolation hospitals would have been efficient. But diphtheria was more or less prevalent in all large towns, the periods of prevalence recurring, not after the manner of measles, at fairly constant and rather short intervals, but at long, uncertain intervals after comparative and often remarkable quiescence. During the first months of an outbreak hospitals might be more useful than later in preventing its spread, of course in conjunction with the treatment which restrained the diffusion of the infection. Having referred to school examinations in infected classes, he said that in Bristol they had not found the difficulty met with in London, of the inaction of some authorities when outbreaks were referred to them. Contrasting smallpox with diphtheria, he said its course and habits made it easier to control, in spite of its high infectivity. A patient either had, or had not smallpox, but he never carried it about in an inert but potentially infective form. The essential conditions of isolation could therefore be fulfilled. The fact which must impress all who studied the progress of the past sixty years was the replacement of broad generalization in regard to the causation and control of communicable disease by intimate study of each disease in detail, and specific adaptation of means to secure success in respect to each. The result was advance. But scientific advance is necessarily slow, and does not satisfy impatient critics. The public might weary of recurring changes in the attitude of scientific medicine towards disease through failing to recognize that every check of reconsidered knowledge is but the backwash of a single wave upon a rising tide.

Sir A. Conan Doyle has taken up the case of Mr. Edalji, who was convicted of maiming cattle at Wyrley, as some of your readers may remember. After three years he was released by order of the Home Secretary, and it may be presumed that this means he is thought to be innocent. All this time the *Medical Press and Circular* has held that he was either a lunatic or the circumstantial evidence, on which alone he was convicted, led to a miscarriage of justice. Sir Conan Doyle reports that Edalji is myopic with astigmatism, and he appeals to ophthalmologists to say whether it would be possible for him to have set forth on a dark night, with neither moon nor stars, to have crossed country for half a mile, climbing fences, finding gaps in hedges, and passing over a broad railway line, to have mutilated a pony which was loose in a large field, to have returned, and done all in thirty-five minutes. Such a task would not be easy with perfect vision. It should be said the man had never worn glasses. The point raised by Sir C. Doyle is interesting. But many people will think it more important that similar outrages took place at the same place while Edalji was in prison.

Among the bills to be brought forward in the coming session, and which have fulfilled the necessary formalities, is one to incorporate King Edward's Hospital Fund and establishing its administration on a permanent basis. H.R.H. the Prince of Wales is nominated President during the pleasure of the Sovereign, and it is further provided that "every succeeding president shall be appointed by and hold office during the pleasure of the Sovereign." The general council of management is to consist of such and so many persons as the President shall from time to time appoint. Thus the King, and with his sanction the Prince, may do just as he pleases, as it may be said he does at present. What then is the need for an Act of Parliament? The people are willing to give their money for King Edward to allot to the hospitals. It therefore seems inadvisable to provoke comment on such an autocratic proposal, or to ask them to endow a future monarch.

Progress of Medical Science.

New York Medical Journal, January 26, 1907.

Empyema of Some of the Accessory Sinuses of the Nose Complicated by an Orbital Abscess.—J. Guttman's patient was a girl of fifteen years, whose initial symptom was toothache followed by a swollen jaw. Later the swelling extended to the eyelid and the author was called to see the girl. Pus was found in the antrum. A radical operation was done on the antrum, the middle turbinal removed in front, and the ethmoidal sinus entered. Pus escaped from the latter cavity. Before the operation there were evidences of an orbital abscess. The latter was opened through the inner canthus and the communication between the orbital abscess cavity and the ethmoidal sinus enlarged by breaking through the lamina papyracea, which had already been partially destroyed by the suppurative

process. The whole process of infection was very short, only forty-eight hours having elapsed from the beginning of the toothache to the swelling of the eyelids. It is not improbable that the primary cause of the onset of the disease is to be found in an inflammation at the root of the tooth, which spread to the maxillary sinus, from there to the ethmoidal sinus, and thence to the orbita' cavity.

Treatment of Chronic Urethral Discharge.—S. L. Gans describes the methods which have commended themselves to his judgment. He uses the term urorrhea to signify the sticky discharge which follows a prolonged or severe attack of urethritis. This is the product of overactive mucous glands or relaxed vessels. All local treatment has a tendency to increase the condition, except in some cases which will respond to the local injection of a few minims of 1-2000 adrenalin solution. General tonics and hygiene are called for, and cold spinal sponges in the morning will soon effect a cure, if the patient can be persuaded to abandon the pernicious habit of constantly "stripping" the penis. The author takes up the details of instrumentation in cases of gleet dependent on a patch or errosion independent of a stricture. Concerning strictures, he says, dilate all strictures except those that are resilient, cartilaginous, irritable, or bleeding, allowing that the technique is correct. Where a stricture reaches a certain point and persistently refuses to dilate further; where there is repeated and excessive bleeding, or urethral fever, then, regardless of the caliber, a cutting operation is advisable. Internal urethrotomy is indicated when the lesion is at or near the meatus, but external urethrotomy or perineal section should always be done when the stricture is at or near the bulb. A departure from this rule is to invite infection, as the bulb represents the base of a U-shaped tube (urethra) with its consequent bad drainage.

The Management of Laparotomy Patients and their Modified After-treatment.—The general conclusions of H. J. Boldt are summarized in the following propositions: No particular preparatory treatment is necessary for patients upon whom it is intended to do an abdominal operation, unless the operation involves the opening of the stomach or the bowels. Stomach lavage is of benefit at the conclusion of the operation. Patients should not be kept unnecessarily under an anesthetic. The application of a tight bandage around the upper part of the thighs, to keep a blood reservoir in the lower extremities, in exsanguinated and very weak patients, is excellent. The same may in exceptional cases be done with one of the upper extremities. These bandages are taken off as soon as the operation has been completed, and thus more blood is thrown into the trunk. The administration of strychnine during and after an operation should be conducted with more care than is usually done. The intravenous infusion of a 0.9 per cent. saline solution should not be too long delayed when the condition of the patient makes it evident that its employment may be of benefit. In instances of large myomata, where the patient has been much exsanguinated by bleeding, it is desirable that the infusion be begun as soon as the patient is fully under an anesthetic, so that by the time the operation has been completed about 1,000 to 1,500 c.c. may have been infused. The application of a very simple dressing over the wound, and the adjustment of a snugly fitting Scultetus bandage made of oxide of zinc plaster; the administration of a dose of morphine if restlessness or pain makes this desirable, the medication then acting as a heart stimulant; the allowing of regular diet and unrestricted mobility within twenty-four hours after the operation, unless specially contraindicated; the getting patients out of bed as soon as possible after an operation; the avoidance of forced catharsis before the first four or five days after an operation unless there is a special indication for it. In instances where resort to vaginal drainage is had, or where it is evident that there will be some secretions intraperitoneally after an operation (purulent cases, and oozing from torn adhesions), the employment of trunk elevation as soon as the patient is put into bed. For this the employment of a bed-lifter such as described, or the placing of high blocks or chairs under the head of the bed, is preferable to back rests.

Journal of the American Medical Association, February 2, 1907.

Diagnosis of Rheumatoid Joint Disease.—The differential diagnosis of chronic arthritis deformans and gout is discussed by J. B. Herrick. He points out that there are many exceptions to the rule that arthritis deformans is always chronic, afebrile, and begins in the smaller joints. In fact, the recurrence or acute exacerbations of supposed chronic rheumatism are frequently arthritis deformans or gout. In the acuter type of arthritis, however, there is not the shifting of the process from one joint to another. The excessive sweating is lacking and cardiac complications are very rare. The acute process is slower to subside than in acute rheumatism. With the passing of time the tendency to deformities begins to be apparent and in the larger sometimes as well as in the smaller joints. Arthritis deformans is more likely to attack the temporomaxillary, sternoclavicular and vertebral joints than rheumatism and there sometimes may be considerable fluid in the joints. Various nervous symptoms, such as burning, weakness, numbness, may be present. The *x*-ray may help the diagnosis. As regards gout, he holds that it is commoner in the United States than is generally supposed and is by no means confined to the "high livers." Beer drinking, lead intoxication, heredity, intemperance in diet, and a sedentary life seem to be the most common causes in this country. The suspicion of gout should be present in all cases of typical rheumatism. Herrick remarks that the typical febrile big-toe attack, or a history of such, excepting tophi, is the most valuable aid to diagnosis. Tophi are usually sought for in the ear. They should be looked for also in the cartilages of the nose and larynx and in the joints. They are often overlooked, he thinks, not only if they are small, but also when they are large and soft. If one watches for the points mentioned, looks out for cardiovascular accompaniments of the disease, studies the uric and phosphorus acid output, and employs the *x*-ray, he can generally make a sure diagnosis. There are, nevertheless, some cases without tophi that are pretty baffling.

The Physiological Action of Alcohol.—W. S. Hall discusses the relation of alcohol to living protoplasm, pointing out that it is a normal product of metabolism of the yeast fungus; that it belongs to the class of substances that are completely metabolized and is passed out because its existence is destructive to the living cell; in short, that it is an excretion toxic to the organism that produces it. An excretion of this type is also toxic to higher organisms, and this is the case with alcohol. Admitting that it is oxidized in the liver and produces heat and that it may lead to decrease in the catabolism of carbonaceous foods, the heat produced is not a normal catabolism, but is simply the result of a protective oxidation, which is insufficient, the toxic action showing in its narcotic effects. The decreased catabolism of carbonaceous and nitrogenous foods following the ingestion of a narcotic is a universal fact depending on the drug effect and giving to the oxidized narcotic no significance as a food. It may be said, he says, without reservation that ethyl alcohol is not a food in the scientific significance of the word.

Alcohol in Its Relation to Degeneracy.—E. S. Talbot holds that alcoholism is often the expression of an existing degenerative taint rather than its causal factor, and that ignoring all but the alcoholic factor in degeneracy is often the source of error. He points out that the effect of alcohol on the individual is much like that of the chronic contagions, but with a greater deteriorating action on the nervous system, and that in its degeneracy-producing action it is aided by poverty and other bad environmental conditions. The routine prescription of alcohol for various ailments is undoubtedly responsible for much inherited degeneracy, and this way an immense amount of harm is done by alcoholic nostrums. The precursor of degeneracy is a neurasthenia induced by alcohol in these cases, and the neurasthenia of the ancestor becomes the neurosis of the descendant.

The X-Rays in Lupus Vulgaris.—H. W. Van Allen has employed the *x*-ray in the treatment of lupus, using for the treatment of the general surface a tube with an air-spark gap of from one to two inches and a distance of the anode of about ten inches, and duration of twenty minutes. Application is made twice a week till the first indication of hyperemia is obtained. This is usually a month or less, and then the treatments are given about once a week for a month longer. After this the patient is told to return in a month, when the surfaces will usually have a healthy pinkish color and nodules can be clearly discerned. The intervening tissue is protected and the nodules are alone treated with a tube of less than an inch air-spark gap, the distance being six inches and the duration twelve minutes. The applications are made three times a week

until reaction takes place, when the cumulative effect is produced, with scabbing and slight ulceration. As soon as the active cautery action begins to subside, he finds the high frequency discharge given off from a low vacuum tube excited by a Tesla coil and resonator, attached to the static machine, to have great value in hastening repair and cicatrization. Other special details are given, but the above are the essentials. He compares the *x*-ray treatment with the Finsen method, pointing out the disadvantages of the latter as regards time required and the need of special personal attention. A table is appended giving the results in fifteen cases, selected on account of the certainty of diagnosis, and giving a percentage of 80 per cent. of cures, with an average duration of treatment of six months and a lapse of time since discharge averaging eighteen months, indicating, he thinks, a permanent cure.

Further Study of the New Infectious Disease.—L. K. Hirschberg defines this disease as an acute infection of sudden onset and unknown bacterial origin, characterized clinically by fever, constipation, absence of blood parasites, agglutination with the usual bacteria, rose spots, enlarged spleen, and tympanites. Its pathology is unknown, as there have been no deaths, and there was no way to ascertain its incubation period from the histories; the onset was always sudden. The duration was from ten to twenty days. Constipation was a conspicuous symptom, and the slowness of the pulse was a striking peculiarity. No epistaxis, chills, or sweating. In no case were there any abdominal tenderness or characteristic eruption; the fever was rapidly ascending, reaching even 105.4° without delirium or nervous symptoms in some cases. Cultures and agglutination tests were failures. The diagnosis is simple; there is little chance to confuse the condition with other diseases; it seems, he says, to be a distinct clinical entity. In all cases thus far reported the patients have recovered without apparent sequelæ, except one, who had, some weeks later, an attack of typical typhoid with Widal reaction. The general management of the disorder, like typhoid, consists in good nursing, attention to diet, and hydrotherapy. The constipation is stubborn and should be closely watched.

The Lancet, January 19, 1907.

Some Limitations of Medical Evidence.—S. B. Atkinson notes that limitations of medical evidence may arise in two directions: First, limitations of medical knowledge, and, second, limitations imposed by the policy of the law. The former restrictions become fewer with the advance of time, research, and medical education. Limitations imposed by rules of law are enlarged much less easily. Modern statutes are notorious for the strictness of their definitions. All definition implies limitations. Limitations of medical knowledge may be relative to the witness concerned or they may be absolute. Thus the diligence, skill, and knowledge of medical men vary from age to age and from person to person. So variable is this range that a man is expected to treat a patient only to the best of his ability and not in the best manner possible by an authority on such matters. Recognizing personal limitations, it is wise for all professionals to be on their guard and to risk no disgrace, when in doubt by a delay in applying to a superior authority at once. Another relative limitation arises when some restriction is imposed upon the medical witness while, wittingly or unwittingly, he is qualifying to give his evidence. Thus when a full physical examination of a person cannot be obtained, or when consent to conduct a post-mortem examination is withheld, there are several matters which otherwise might be made patent, but which will in the circumstances remain obscure. A second variety of limitation owing to the lack of sufficient medical knowledge is not relative to the medical witness personally, but is a general inability to make a positive declaration owing to the uncertainty, insufficiency, or inconclusiveness of the facts available. Even real authorities in this variety of limitation may have to confess that they do not know certain facts, or will, when pressed, offer a very guarded opinion. The last variety of limitation is that imposed by the rules and policy of the law; it arises on account of the essential strictness of the presumptions and of common law or statutory definitions which become more rigid with modern legislation. Thus crimes must be defined in exact terms and the medical facts must, to be of any avail, be capable of being pigeon-holed—counsel will endeavor, as they did in the bad old days of special pleading, to fit the facts into a loophole if possible. Loose popular phraseology has led to occasional surprise in this connection; thus, in a moment of righteous anger we may say of drunkenness: "It's a crime," but as a matter of fact the law books do not recognize it as such, although it may incidentally or consequentially lead to the commission of crime.

Opsonins and Treatment by Bacterial Vaccines.—J. L. Bunch discusses the opsonin theory and in closing his paper refers to two cases, one of lupus of the face and the other of testicular tubercle cured by injections in accordance with this theory. Nothing particularly new is brought out. Concerning the "negative phase," which is such an important factor, the author says that if the right dose has been given the phase will not be too marked or unduly prolonged and will soon be followed by a well-marked positive phase, and in succeeding inoculations the negative phase will be still less. But if too large a dose be given or it be injected when the index is falling, the positive phase will make its appearance very late or not at all. The author purposely lays stress on this point because some of the first injections which he gave more than eighteen months ago were too large, and he has known an injection of 1-500th or 1-400th milligram to be followed by a negative phase which was so marked as to last for weeks. It seems to be generally agreed that only the minimal dose must be employed which will produce a satisfactory response, and this must not be increased until it ceases to produce its effect. The dose, moreover, must not be repeated until the effect of the preceding dose is passing off. If it were possible to produce a summation of positive phases it would be advantageous to give successive doses at short intervals, so as to produce a maximal favorable effect, but such summation is not possible in the case of tubercle. Each inoculation, therefore, produces its effect independently, and it remains to take the greatest advantage possible of the increased elaboration of protective substances which the artificial stimulus has produced. It is obvious that this can only be done by bringing the protective substance as closely as possible into contact with the bacteria which are the cause of the disease. This is simple enough when the bacteria lie within easy access of the blood stream, but when they are flourishing in the tissues in circumstances most favorable to their growth, remote from the blood stream and in contact only with a lymph which is naturally poor in antibacterial substances, the mere increase of the opsonic power of the blood is not sufficient. The opsonin must be brought into direct action with the bacilli in the diseased focus, and this can only be done by increasing the lymph flow through that focus. When it is situated near the surface this may best be brought about by the application of counter irritants, rubefacients, or heat, either dry or moist, in the form of hot-water bottles, hot-water tins, or the commonly used hot boric fomentations. When the focus or disease is in a joint Bier's method of passive congestion is one of the greatest service. The effusion of lymph produced by each of these methods is very considerable, and, in addition, the viscosity and coagulability of the blood can be greatly diminished by the internal administration of decalcifying agents, such as citric acid.

Scepticism in Therapeutics.—A. H. Bampton declares that man is an organized collection of differentiated and highly specialized cells, and that cellular action is governed by physical laws and chemical processes and is profoundly influenced by slight causes, and that nine-tenths of disease is due to the interaction of cells and their products and germs and their products, chemistry being the interpreter of these phenomena. Barely 50 years ago belief in drugs and energetic treatment was the faith and practice of the majority of the profession. It was the rise of the pathological school and the study of morbid anatomy that shook the faith of the succeeding generation of practitioners, viewing only the last stages of disease and seeing structural alteration in the mass. It was thought unreasonable to imagine that any pharmaceutical product could have any influence whatever on such profound structural changes in vital organs. It was argued that the cause of many diseases being unknown, therefore the remedies were irrational. But we do not know but that remedies given early may affect some of these earlier cell alterations, which eventuate in familiar gross pathological changes. So the administration of the remedies is logical and proper. The author remarks that if the mystery of life is to be solved it will be by the experimental examination of the simplest form of life. The discovery that every tissue, every cell, has its own special ferment, is of far-reaching importance

in explaining much that was mysterious in physiology and pathology and accentuates again the importance of chemistry in explaining vital phenomena. When medicine and physiology are written anew, we shall be told the relations that one ferment bears to another. And it is by virtue of this special ferment that each cell is able to select out of the food-stuffs such material as it can transform into energy. The corollary of this is true, that an organ or tissue may fail to perform its function from lack of special fuel to make the ferment. It has been pointed out that during the involution or atrophy of an organ the symptoms which arise may be due to the absorption of the tissue and its passing into the general circulation; absorption of kidney tissue, for example, produces increased arterial tension; liver substance lowers it. Recently, the involution of an enlarged thyroid has been noted to give rise to all the signs attributable to large doses of thyroid extract. Finally, the author expresses the hope that as pharmacology advances, mechanical or empirical prescribing will become less and less frequent. At present we know that drugs produce their effects either by chemical combination or by their physical properties interfering with oxidation processes, as sand puts out a fire, and their ability to penetrate a cell may depend upon the size of the molecules of which they are composed. Instances of chemical combination are shown in the exhibition of alkalies in diabetic coma and sulphonal poisoning, in the action of sulphate of soda in carbolic acid poisoning, and of sodium hyposulphite in combining with prussic acid to form the nonpoisonous sulphocyanide. The most powerful narcotic substances are those which combine a very slight solubility in water with a very high solubility in ether, olive oil, or brain lipoid. The cerebral cells are more sensitive to alterations in their composition than other cells and they contain a much larger percentage of "lipoid matter" or fat, so that these drugs tend to accumulate in them. Here we have an instance of the physical action of remedies.

Some Observations on Fat Necrosis.—J. E. H. Sawyer has noted eight cases of fat necrosis in a two years' service as pathologist to the general hospital at Birmingham, and summarizes their clinical histories and autopsy findings. Three occurred in connection with acute hemorrhagic pancreatitis; two with subacute and one with gangrenous disease of the pancreas; one followed hydrochloric acid poisoning and one occurred in connection with mitral disease. The paper describes the distribution and appearance of the areas of fat necrosis and the changes found in the pancreas. Analysis of the fat particles was made in one instance, and it was found that they consisted of the calcium salts of a mixture of fatty acids superfatted. There was no glycerin, leucin, tyrosin or any other amido acid found. Consequently they could not be due to proteid decomposition. In one instance bacterial cultures were made of the fat necrotic areas, which were found to be sterile. Tissue sections in other cases showed no bacteria. In some cases examination was made of the fluids from the pancreas, and associated peritoneal cysts. In all of these the *Bacillus coli communis* was invariably found, associated with various other organisms. The author believes that in order to produce fat necrosis some other factor must be in evidence than mere obstructions of the pancreatic duct. It would seem that some destruction of pancreatic tissue is also necessary. Then there occurs a leakage of the pancreatic secretion into the surrounding tissues and its fat-splitting ferment produces the necrotic changes.

British Medical Journal, January 19, 1907.

Yellow Fever in the Chimpanzee.—H. W. Thomas reports the following experiment: Fifty-seven stegomyia mosquitos were allowed to feed on two yellow fever patients. On the twenty-first day thereafter the twenty-nine surviving insects were allowed to bite a chimpanzee. In twenty-seven hours the animal's temperature began to rise, and during the succeeding nine days he went through what was regarded as a benign attack of yellow fever from which he recovered. Mosquitos were allowed to feed on him during the infection period, it being the intention to apply them later to a nonimmune individual to complete the cycle of man-chimpanzee-man. Details of the experiment are given in the original paper. [What all this proves or is meant to prove, is, in the abstractor's mind, a bit hazy.]

Papain in Malignant Growths. C. W. Branch relates his personal experience in five cases seen at St. Kitt's West Indies. A papain emulsion was injected under local anesthesia by partial freezing The emulsion was made just as it was about to be used, and contained 1 gr. in every 5 minims of cold distilled water. From 5 to 20 minims of this emulsion were introduced at one time, according to the size of the nodule or tumor; ½ gr. was the smallest dose given. This destroyed a hard nodule about the size of the kernel of an almond. The instrument used in all the injections was a Gee's hypodermic syringe fitted with its largest needle. This was sterilized and a drop of emulsion made to appear at its point before its insertion. If the tumor was large, the needle was made to pause two or three times while some of the emulsion was ejected, so as to establish two or three foci of action along the one line of insertion. Only a slight puncture was made. The operations were repeated at intervals of from two to four weeks. Following the injections a burning sensation came on and a curious feeling as if some small animal was nibbling at the flesh. Nausea was at times present. The tumor softened around the site of puncture in two or three days. There was a slight rise of temperature. In about ten days the tumor began to discharge freely through a small hole a thick, greenish stuff, but the discharge ceased in a week or two, at which time the growth was found noticeably smaller. The general results were favorable, but the cases were too few and too recent to permit of any sweeping conclusions. The author states that it seems possible that papain injections may be admissible in the treatment of some cases of primary cancer and other tumors. He has lately come across a statement that papain has been applied, he supposed externally, to epithelioma; but there was no mention of the result. It is very likely that it was satisfactory. He rubbed the fresh juice of the root of the papaw tree on two small growths, neither of which was malignant. They were both entirely eradicated by a few applications. The little operations were perfectly painless, surpassing in this respect similar ones done with sodium ethylate. Perhaps leprous tubercles might be removed in this way with less pain and disfigurement than by the acid juice of the cashew.

Immediate Microscopical Diagnosis of Tumors During Operation.—This general question is considered by C. B. Lockwood, who commends the following technical method as elaborated by E. H. Shaw. The method may be divided into two parts: (1) The arranging and fixing up of the apparatus required. The microtome must be fixed on a firm table, and all the instruments arranged in a convenient manner. A mental survey of the cutting, mounting, and staining of a section is then made, in order to make sure that everything is present and in its proper place. This ensures that no time will be wasted when once the process is begun. (2) Preparation of the microscopic section. (a) The selected piece of tissue received from the surgeon is placed directly on to the brass disk of an ether-freezing microtome, and is surrounded by gum solution. (b) The tissue and gum are frozen, and sections made by a razor on a carrier. (c) The sections are transferred to a dish of cold water, and, after separating them with a glass rod, a suitable section is lifted out. (d) It is dipped for a moment into pure methylated spirit, and (e) Then placed in another larger dish of cold water; the currents set up by the spirit in the water cause the section to spread out flat. (f) A glass slide is dipped in the water under the section, and the latter is lifted out as the slide is slowly drawn up out of the water again. (g) The water is drained off the slide, and a drop or two of stain (Löffler's methylene blue) is allowed to fall directly onto the section. (h) A thin cover-glass placed on the stain and section after three to five seconds; it is lightly pressed down so as to drive out excess of stain; this is then blotted off, and the specimen is ready for examination under the microscope.

Etiology and Prophylaxis of Dracontiasis.—R. T. Leiper refers to a common ailment in West Africa. He believes that most of the cases are infected from the water of village ponds through an organism which lives on the cyclops. The author began his experiments by selecting cases of the disease in which the vesicle caused by the inoculation by the fully developed parasite was still whole or had recently burst. If a damp compress was bound for a few hours over this area it was found on removal to be smeared with an almost solid mass of embryos The details of his experiments are too elaborate to be reproduced here. Leiper believes that the young must be discharged directly into fresh water soon after the parent worm has succeeded in creating a break in the overlying skin and before the wound has become markedly septic. The embryos must find a cyclops within a

few days. They must, moreover, succeed in entering its body cavity. Five weeks later they will have developed into mature larvæ. These must, thereafter, be taken into the human stomach, and having been set free from its host by the gastric juice, reach the connective tissues by penetrating the gut wall. The life-cycle of the parasite will necessarily be broken: (1) By the death of the embryos, either from sepsis while still within the parent worm, or after their discharge, by saltish water or drying. (2) If cyclops are not present in the water, or if the infected cyclops die or are not taken into the human stomach. (3) If the larvæ, ingested by the final host, are immature or fail to escape from the chitinous sheath of the cyclops. Though they do gain their final habitat, the cycle will still be incomplete if (4) there are not both males and females among the matured adults, and if in their wanderings the females are not impregnated. It will at once be seen from the above summary that the isolation of infected man from healthy cyclops and of infected cyclops from man must be the object of any organized effort to stamp out dracontiasis.

Berliner klinische Wochenschrift, December 31 and January 14, 1907.

The Effect on the Rabbit's Aorta of Intravenous Injections of Suprarenal Extract.—Kaiserling states that after considering the results published by the many authors who have experimented on the etiology of arteriosclerosis by injecting suprarenal extract into rabbits, he was impelled to repeat the observations on his own account. Although most of the workers have reported the production of lesions more or less like those of human aortic atheroma, there are many minor differences in their published statements, but Kaiserling was astonished to find that, in a series of eight rabbits which he treated according to the recognized technique, the results were practically negative as regards the production of aortic lesions, even though in the one case forty-four injections, amounting to 19.3 c.c. of 1-1,000 suprarenin hydrochloride were given in the space of ninety-four days. He, therefore, assumes a skeptical attitude toward the question, and expresses the opinion that much larger series of results must be reported before the etiological relationship between such injections and aortic disease in rabbits can be accepted. He suggests that it is possible that rabbits are more subject to spontaneous calcification of the aorta than is generally supposed, and describes a case of this sort which he himself discovered by accident. It is also possible that questions such as those of diet, of age, and of breed may require consideration, and he recommends that observations be made on large series of animals to determine whether spontaneous aortic disease occurs, whether other methods of raising the blood pressure than the use of adrenalin evoke similar changes, how other animals behave in this respect, etc.

Myasthenia Gravis Pseudoparalytica.—Sitsen says that so far about thirty cases with autopsy of this disease have been reported. The examination of the material has been rather insufficiently described, he says, and he urges that in future cases greater care should be used to record all possible abnormalities. Of the cases tabulated by the author the one type of lesion that appears most prominently (in nine cases) is an involvement, in one way or another, of the lymphatic system, and Sitsen suggests that in new cases an endeavor to trace a relationship between lesions of this system and the disease be made. In a case of his own there were found small recent hemorrhages in the cerebral cortex, lung, and liver, there was hematin-stained lymph in the perivascular lymph spaces of the pons, there were accumulations of leucocytes in the liver, there was slight enlargement of the spleen, there was degeneration of the renal tubules, a colloidal goiter, and an increase in the leucocytes of the blood.

Münchener medizinische Wochenschrift, January 1 and 8, 1907.

Methods for Reinforcing the Knee Jerk.—Rosenbach reviews the various methods, such as Jendrassik's and Krönig's, which are intended to facilitate the testing of the knee jerks by diverting the attention of the patient, and so effecting the desired relaxation of the lower extremities. None of these methods is altogether satisfactory, and Rosenbach has found that the following expedient is applicable to the greatest number of cases. The patient is given either a book of considerable size, or a newspaper, and is told to read aloud. The muscular effort required to hold the volume or paper, and the mental attention involved in the reading, produces the ideal conditions for obtaining the knee jerk, and the method is applicable even to children who are able only to name the letters. In some cases it is difficult for the patient to cross the knees owing to some physical cause, such as obesity, ankylosis, or unconsciousness. For such cases the following expedient, first suggested by Guttmann, is recommended. With the patient lying flat, a towel is passed under the calf of the leg and the limb is raised a little from the bed by this means. A second towel is then passed under the thigh a little above the knee, and the thigh is elevated so that an obtuse angle is formed at the knee and the entire limb is supported by the two towel loops. The patient, if conscious, is directed to allow the leg to rest with all its weight on the supporting slings.

The Early Diagnosis of Pulmonary Tuberculosis.—Arnsperger says that although the value of the *x*-ray as a means of determining the extent of advanced tuberculous lesions and of observing their progress is universally admitted, the method has not yet received the recognition it deserves for the purpose of diagnosing incipient cases. The normal radiographic picture of the chest is much less subject to individual variations than is the picture obtained from the physical signs, and after a little experience has been gained the use of the *x*-ray is found a most trustworthy adjuvant to the customary diagnostic measures. The author discusses the type of tube to be employed, and states that he attaches great importance to the use of a properly constructed diaphragm, which should preferably be of the iris variety. He then describes the evidences of apical infiltration that may be discerned in the earliest stages, and observes that he disagrees with those authors who have found that restricted mobility of the diaphragm on the affected side is a frequently encountered sign in incipient tuberculosis. He recommends the *x*-ray examination especially in selecting cases suitable for sanatorium treatment, and points out other advantages that should cause it to be more universally resorted to, although he admits that during the early stages it should be used only in conjunction with the customary methods of diagnosis. In another article on the same subject by Pforringer and Bunz, the use of the rays is also well spoken of, and, like Arnsperger, these authors state that they do not attach very much importance to lagging of the diaphragm as an early symptom. The chief value of the radiographic method seems to lie in the ability by its means to confirm the correctness of a diagnosis made in other ways.

The Treatment of Gastric and Intestinal Hemorrhages with Fluid Gelatin.—Mann reports excellent results in the treatment of this condition by the internal administration of a preparation of fluid gelatin. The histories of nine cases are briefly abstracted to show the prompt effect of the remedy in such conditions as typhoid fever, gastric carcinoma, ulcer of the stomach, and melena. In none of these cases was any other medication resorted to except the gelatin treatment, yet prompt cessation of the bleeding followed in all except one case, which was an unusually severe typhoid infection. In this instance the autopsy revealed the presence of extremely numerous and deep ulcers, so that it would have been rather too much to expect any remedy to effect a cure. The formula for the gelatin mixture is as follows: 20 g. of gelatin is boiled during six hours with enough water to make 180 c.c. It then remains fluid and 2 g. of citric acid is added. It may be flavored with a little syrup of orange and is given in doses of one or two tablespoonfuls every two hours.

The Presence of Diphtheria Toxin in the Blood of Patients.—Fraenkel says that Uffenheimer has stated that on injecting serum obtained from children suffering from diphtheria into guinea pigs he obtained lesions in the animals, such as edema of the skin over the thorax and abdomen and pronounced hemorrhagic lesions, which appeared to indicate that free toxin was present in the blood of these patients and that therefore this toxin should be neutralized as promptly as possible by the injection of antitoxin. Fraenkel repeated these experiments with blood obtained from twenty-three cases of the disease, but on making a post mortem examination of the animals, which were killed forty-eight hours after the injection, he was unable to discover in any except one alterations that could be ascribed to the introduction of diphtheria toxin. In the case of the one animal that did not give a wholly negative result Fraenkel believes that the reddening and swelling of the abdominal skin produced was an accident due to the possible puncture of a larger blood-vessel by the injection needle. The author does not attempt to explain the discrepancy between his results and those of Uffenheimer, but affirms his conviction that the circulating blood in cases of diphtheria does not contain sufficient toxin to be demonstrable on the injection of small amounts of serum (about 1 c.c.) into guinea pigs.

Book Reviews.

A Syllabus of Materia Medica. Compiled by Warren Coleman, M.D., Professor of Clinical Medicine and Instructor in Materia Medica and Therapeutics in Cornell University Medical College; Assistant Visiting Physician to Bellevue Hospital. Third Edition, Revised to Conform to the Eighth Decennial Revision of the U. S. Pharmacopœia. New York: William Wood & Co., 1906.

This edition has been revised to bring it into agreement with the late revision of the U. S. P. At the same time the requirements of the various State Boards of Examiners throughout the country have made it necessary to include all the official preparations. Most of the unofficial drugs have been omitted. The book is a useful compilation and will prove a serviceable companion to any textbook on materia medica.

Retinoscopy (or Shadow Test) in the Determination of Refraction at one Meter Distance, with the Plane Mirror. By James Thorington, A.M., M.D., Author of "Refraction and How to Refract"; Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Ophthalmologist to the Elwyn and Vineland Training School for Feeble-Minded Children. Fifth Edition, Revised and Enlarged. Fifty-four Illustrations, Ten of Which are Colored. Philadelphia: P. Blakiston's Son & Co., 1906.

This valuable work now appears in its fifth edition, thoroughly revised. The author has carefully described this method of objective examination of the eye in as brief and concise a manner as possible. The source of light and the most favorable surroundings and conditions for the examination are discussed. The various appliances necessary are mentioned and the phenomena observed are elucidated. A sufficiently comprehensive index accompanies the work. The volume, which contains only sixty-seven pages, can be studied with profit by any medical man who wishes to obtain quickly a working knowledge of retinoscopy.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, U. S. A. Vol. III, Sixteenth Series, 1906. Philadelphia: J. B. Lippincott Company, 1906.

The third volume of this year's issue of "International Clinics" contains much that is interesting and valuable. Among the most important articles is that of Bradford of Boston on the Hyperemia Treatment of Swollen Joints, an excellent résumé of the subject, illustrated with photographs of cases, apparatus, etc. Saingéry's review of Fournier's recent modifications in the treatment of syphilis is also of especial interest, as it discusses a subject which has come up recently with renewed force, the question as to the proper means of preventing such sequels as locomotor ataxia, etc. The other three articles on medical treatment—by Stevens of Philadelphia on Acute Pleurisy, by Patton of Chicago on Bronchitis, by Katzenbach of New York on Cardiac Dilatation—are full of practical points attractively presented. An article of exceptional interest is that of Pirie of Edinburgh on "Life in the Antarctic from a Medical Point of View," the author having taken part in the Scottish Antarctic Expedition of 1902-1904. The article on Leukemia and Sarcomatosis by Banti of the "University" of Florence (the Institute for the Advancement of Science of Florence is probably meant) discusses the probable nature of the leukemias which, according to the famous Italian clinician, are infectious sarcomatoses, though he has not been able to find their specific agent.

Aids to Obstetrics. By Samuel Nall, B.A., M.B., D.P.H. Cantab., M.R.C.S. England, etc. Sixth Edition New York: William Wood & Co., 1906.

There is probably no subject for which a compend is less needed than obstetrics. Still, if a student feels that he requires a help in preparing for examination he will find this little book of service. In the present edition a few minor alterations and additions have been made, otherwise the book remains unchanged.

L'Autointoxication Intestinale.. Par le Dr. A. Combe, Professeur à l'Université de Lausanne. Paris: J.-B. Baillière et Fils, 1906.

Dr. Combe has written an exceedingly practical, at the same time a highly scientific, book on autointoxication from the intestine. A lecturer on diseases of children, he has taken up within the past few years the study of intestinal diseases in a large number of adults, whom he saw in private practice. In the course of this study he has developed certain original methods of diagnosis and treatment, and has paid much attention to diet. While he acknowledges his indebtedness to Strauss, Albu, von Jaksch, and others, his work has been carried on independently and his results are carefully recorded. The chemistry, bacteriology, etiology, pathology, and diagnosis of intestinal autointoxication form the first part of the book, while the rest is taken up by a detailed study of the treatment of this condition. In the chapters on diagnosis will be found all the modern methods of studying the various autointoxications through the medium of the urine, including several methods original with Amann and Combe himself. Under the heading of Treatment the author presents an admirably written, practical, and systematic study of all the measures that may be useful in combating intestinal autointoxication. Full and explicit directions are given for each therapeutic method, and detailed ménus and dietaries are introduced, making the handling of this class of cases plain sailing for the practitioner. Even the modes of preparing and cooking certain foods are described, and among other articles Combe recommends a number of popular American "breakfast foods." Space will not permit to enter further into details, but we can strongly recommend this latest book on autointoxication to physicians who are progressive enough to study their cases and to apply modern dietetic and hygienic measures in the treatment of disease.

The Practical Medicine Series. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D. Volume VII. Pediatrics. Edited by Isaac A. Abt, M.D., Assistant Professor of Medicine (Pediatric Department), Rush Medical College. Orthopedic Surgery. Edited by John Ridlon, A.M., M.D., Professor of Orthopedic Surgery, Northwestern University Medical School, with the Collaboration of Gilbert L. Bailey, M.D., Instructor of Orthopedic Surgery, College of Physicians and Surgeons. Series 1906. Chicago: The Year Book Publishers, 1906.

The seventh volume of this popular series of year books continues the series of 1906, the previous volumes of which have been noticed in this column. It deals with two closely allied special branches, pediatrics and orthopedics, and is a concise epitome of progress in both these fields. The general method of treating the subject is the same as in the other volume, and the book is replete with useful and practical data and summarizes the work done during the past year. Nothing very startlingly new has developed in the field covered by this volume in the year 1905, but the book records the slow and painstaking trend of research along various lines which may lead to much that will be of value.

Guide Pratique Pour le Choix des Lunettes. Par le Dr. A. Trousseau, Médecin de la Clinique Nationale des Quinze-Vingts; Médecin en Chef de la fondation ophtalmologique Adolphe de Rothschild. Deuxième Édition. Paris: E. R. de Rudeval, 1907.

The author of this little work, which appears in a second edition, endeavors to give the essentials of the knowledge required for the satisfactory fitting of glasses in the simplest way and in the fewest words possible. The information is contained in one hundred 4x6 pages. The indications for the use of glasses in youth, adult life, and old age are first set forth. The quality of frames and lenses required is mentioned. Forms of refractive errors are then described. Subjective and objective methods of examining the eyes are explained. Then follow short chapters on hypermetropia, presbyopia, aphakia, myopia, astigmatism, anisometropia, and the visual requirements for military service. A short index concludes the work.

The Masters of Fate. The Power of the Will. By Sophia P. Shaler. New York: Duffield and Company, 1906.

It is always inspiring to read of the achievements of those who have done great things, but it is doubly so when the doers were handicapped by the greatest of all obstacles—ill health or bodily infirmity. Mrs. Shaler presents in charmingly written narrative more or less extensive accounts of the struggles against physical ills of a very large number of those who have contributed to the world's progress—and it is astonishing to realize how much of it has been due to the toil of those who had every excuse to remain mere onlookers. The list of illustrious invalids is indeed a long one, and includes many names which to the ordinary reader do not connote the idea of chronic illness or disability. The difficulties under which Milton, Heine, Stevenson, Mrs. Browning, Darwin, and many others labored are well known, but Mrs. Shaler reminds us that Alfred the Great, Kant, Pasteur, James Watt, Nelson, and Parkman were but a few of the many, much of whose work was done under conditions that the average mortal would consider prohibitive. A sympathetic interest attaches to the author's desire to place on record the adversities that have beset so many great men, for her husband, the late Prof. Nathaniel S. Shaler, was the victim of a long series of physical burdens that, in view of all that he accomplished in his profession, renders him well worthy of high rank among the "Masters of Fate."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 17, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THE evening was devoted to a consideration of "Open-Air Therapeutics."

Open-Air (Roof) Wards on Metropolitan Hospital; Details of Arrangement and Administration; Class of Cases to be Treated.—Dr. W. P. NORTHRUP read this paper and presented illustrations. He said that the open-air treatment had come to stay, and the managers of hospitals, the medical staff, the nursing staff, the professional staff, and staffs in general were now using it systematically. After one year's observation of the out-door treatment at the Presbyterian Hospital the results had been so good that they were now building on the roof a structure which was to cost $15,000, and this, too, in an unendowed hospital. This showed that the systematic open-air treatment of patients was of value and had come to stay. Dr. Northrup then gave the details in part of the structure and management of the hospital. The medical pavilion of the Presbyterian Hospital was demonstrated on the blackboard, and the old solarium was shown, being the dead end of a long shaft that ventilated the cellar. Conditions were now changed. Concrete or cement, four inches in thickness, had been placed on the roof, and over this boards or flooring. The structure that was raised upon this was of steel throughout. He closed his remarks by giving a few rules for the management of this structure on the roof.

Open-Air Treatment of Septicemia in Lying-in Hospitals.—Dr. WILLIAM S. STONE read this paper. During the period Dr. Stone was connected with the New York Lying-in Hospital he had daily opportunity of observing the course of severe puerperal septicemias treated in the glass-covered solarium as compared to the course of the disease in the closed wards, and he gave a few general conclusions based on his own observations. From the patient's point of view it was surprisingly satisfactory. The restlessness and delirium were less frequent and less marked. To the casual and untrained observer the sight of these patients on the roof under their green-lined sunshades might suggest a number of well-to-do convalescents enjoying the advantages of a southern climate, rather than tenement dwellers filled with unnumbered streptococci striving to destroy their host. Like typhoid fever, puerperal septicemia was accompanied by high fever, whether treated in the open air or in the closed ward, but in some cases the duration of the fever seemed to be shortened, and in all cases was better borne as expressed by the pulse and temperature. Pneumonia appeared to be less common and more transitory when it did occur. One of the strongest impressions made upon Dr. Stone was the difference in the general appearance and strength of the patients soon after the disease had run its course. Some cases got well, about which even the most sanguine observer would ordinarily only express a hopeless prognosis. The general conclusion that the reader of the paper drew from these observations was that any lying-in hospital that failed to provide suitable accommodations for the open-air treatment of child-bed fever was lacking in one of the most important means for promoting the comfort and the saving of lives that were intrusted to their care.

Fresh-Air Treatment in Hospital Wards.—Dr. W. GILMAN THOMPSON read this paper. (See page 213).

Open-Air Treatment in Psychiatry.—Dr. WM. MABON, superintendent Manhattan State Hospital, Ward's Island, read this paper. In June, 1901, the late Dr. A. E. Macdonald introduced tent life for the care and treatment of the tuberculous insane at Ward's Island, and three years ago the late Dr. Emmet C. Dent inaugurated the open-air treatment for the acute insane. The camps now used for the acute insane were situated on high, dry ground, which sloped gently toward the waters of Hell Gate, giving a southern exposure and an ocean breeze. The rush of water through Hell Gate and the passing of vessels of navigation through the channel made a scene varied and picturesque, relieving the mind of ennui of many otherwise tedious and wearisome days. The average period of residence in camp life for each acute case was about three months, so that in a year the present capacity accommodated 400 patients, or about 50 per cent. of the entire number of admissions for women. Drawing from the poorer classes of people in the crowded districts of Manhattan Island, stress and strain with physical disability must of necessity enter very largely into the etiology of a large proportion of their acute and recoverable cases. In the 150 cases treated in two of their camps, examination upon entrance showed the hemoglobin to be as high as 95 per cent., as low as 55 per cent.—an average of 70 per cent. In addition to the hemoglobin reduction, the other evidences of marked physical breakdown were constant reduction in weight and evidences of decided disturbances of the gastrointestinal tract. Sleep was insufficient, and delirious states were very frequent. The indications for treatment in these cases were usually clear, and the camp life met the situation better than anything yet tried. He gave abstracts of a few cases to illustrate the results of this method of treatment. Gain in weight was most pronounced. The percentages of the various forms of insanities under treatment in the two camps connected with the reception service were: manic depressive or exhaustive types, 40 per cent.; dementia præcox, where the general health demanded individual attention, 30 per cent., and the alcoholic, hysterical, depressive, and anxiety types, 30 per cent. Among the admissions were a comparatively large number of the exhaustive type occurring during the puerperium, and the majority of them did extremely well under the method of treatment. The most marked improvement under camp treatment occurred in the infective and exhaustive groups, the manic depressive cases, and the undifferentiated depressions. Cases of marked deterioration following overstrain were oftentimes much improved by camp life. After the patients had been under treatment sufficiently long to improve the general health, it was noticed that in the recoverable cases the insanity was either well on toward recovery, or they were in a position to accurately make a prognosis. In the group of cases where exhaustion was the main etiological factor there was no more important restorative than the reestablishment of the proper amount of sleep. Under treatment in the camp, the constant exposure to fresh air and sunlight very frequently brought about a more normal condition. It was emphasized that no drugs were used to relieve the insomnia. The hot pack and the continuous bath, in connection with the open-air treatment, were far more efficacious, trustworthy, and desirable. Aside from the hygienic advantages from these camps, the moral effect upon the insane had considerable influence toward their recovery. The freedom from restraint of bars and locked doors was appreciated to such an extent that vacancies in the camp brought a premium among the more intelligent class of patients, and it was to be wondered at when "scarcely more than a score of years ago our asylums were still prison-like structures, gloomy without and gloomy within. With few exceptions, the walls were guiltless of ornamentation, and the barred windows and locked door, the crib bed, the massive furniture fastened to the floor, and the dozen or more inhuman devices for mechanical restraint, made up a picture well calculated to strike terror into the heart of the newcomer and to fill with despair the unhappy victim of prolonged incarceration." Dr. Mabon closed his paper by stating that the experience of the Manhattan State Hospital for the past five years showed conclusively that the open-air treatment was particularly beneficial for the following classes of the insane: (1) the tuberculous; (2) the feeble and untidy; (3) the retarded

convalescent; (4) the acute insane, in whom the psychosis was associated with anemic blood states, delirium, and loss of sleep.

Dr. Alfred Meyer said that some might be present who attended a meeting held in the Academy a few years ago when the subject of tuberculosis and its treatment was considered; at this meeting Mr. Devine stated that he heard for many months the need of educating the masses regarding the transmission of tuberculosis through the sputa, but, after a certain experience of his in Albany, he thought it would be wise first to educate the medical profession. This same, he thought, could be applied to the subject now before them, fresh air and sunlight. Even in the section rooms, if one of the doctors opened the window, he was liable to be called a fresh-air fiend or crank. Dr. Northrup was doing educational work where it was at present most needed—among the medical profession. Theoretically, all agreed with it; as a rule, it seemed to Dr. Meyer, they had adopted it in theory, but had not applied it in practice. The question of overheating was related to this subject; it seemed to be a national defect to overheat, particularly in the winter time and in places of public amusement. There seemed to be, as well, a prevailing dread of rain and snows. Dr. Meyer believed there was less danger from rain and snow than when the sun was shining, with the dust flying in the eyes, mouth, throat, and perhaps the lungs. If a child had diphtheria he should be covered with blankets and have plenty of fresh air; it was not necessary to have draughts in the room where the child was lying, but plenty of good, fresh air should be allowed the patient. This same could be applied to cases of neurasthenia and convalescence from scarlet fever. A bed-ridden case of sciatica, and other chronic diseases, should be treated by placing near the open window. Surgical diseases should be more frequently treated by this method, and he referred to Dr. Halsted's cases of tuberculous joints treated in the outside air. There was great difficulty experienced in supplying the proper amount of fresh air in hospital wards. A larger number of patients would be benefited by a free change of air compared to those which might possibly be injured. He quoted Mr. Dooley's statement, which was quite apropos of this subject: "If the doctors would open fewer bellies and more windows there might be a fewer number of Christian Scientists." He called attention to the results obtained by the out-door life at Flick's sanatorium at White Haven, Pennsylvania, at the State Sanatorium in the Adirondacks, at Bedford, Massachusetts, and other places. He also called attention to the building of piazzas in country homes and to the utilization of fire escapes in the crowded cities, and how to treat these patients on the roof of their own houses in the fashionable parts of the city.

Dr. David Bovaird, Jr., said that emphasis should be placed on the fact that not only fresh, but cold air was necessary. The value of cold air and fresh air had been brought home to him in dealing with children suffering from diarrheal diseases. Children suffering from severe ileocolitis, if they could be kept alive until the beginning of October, could almost be guaranteed a recovery, and this was due to the change in the temperature of the air during the fall months; this tended to give these children appetites, improved their digestion, and enabled them to gain upon the disease. This autumn he had occasion to note the changes that occurred in the Presbyterian Hospital. At the end of the summer there were many poor, anemic, wasted children as the result of various diarrheal diseases; their lives seemed to hang by a thread. But with the advent of autumn, the appetites became good, digestion improved, they slept better, and the contrast was very marked, all due to the change in the temperature from the summer to the fall months. Fresh air and cold air were agents of great therapeutic value, but should not be used universally. The change in ventilation had done away with so-called hospitalism. A few years ago if a child was kept in the hospital four or five weeks he became flabby and became the subject of hospitalism. To-day the best-looking child, on the other hand, was the one who was the oldest inhabitant of the hospital by reason of the change in matters of ventilation.

Dr. Henry Piffard said that because they required a minimum of sunshine in summer, and a maximum of sunshine in winter, the exposure of solaria for tuberculous and other patients should not be directly East and West, as Dr. Northrup had demonstrated on the board. He referred to the epidemic of typhus fever some years ago, when he was an interne at Bellevue Hospital. The wards became so crowded that the island was utilized for the overflow, and they were there placed in tents. The result was that the mortality was less by one-half than it was in the hospital wards. He also recalled some recent visits made to places near New York City where the patients went "back to Nature," going about perfectly nude, etc.

Dr. Robert J. Wilson said that they had been forced to treat 400 cases of scarlet fever, bronchopneumonia, and measles between April and October in the open air, and these cases did far better than those within the closed wards.

Dr. Louis Livingston Seaman called attention to the fact that all over the tropics, in the Arabic cities, the out-door system of treatment of diseased conditions had been in vogue, even before the days of the Romans. This was also in vogue in the days of Solomon, and in Jerusalem.

Dr John H. Huddleston referred to the epidemic of typhus in 1802 in this city, when so many of the cases were treated on Blackwell's Island. Many were placed in tents, and they all did exceedingly well. None of the orderlies, the nurses, or visiting physicians suffered from the disease. There were some disadvantages and risks attached to this treatment which should not be lost sight of. For instance, it had been his misfortune to see two bad results; two children had been placed on the balcony during convalescent pneumonia, and in both sunstroke developed as a result of the exposure.

Dr. William P. Northrup called attention to what education would do, there being so little spitting in this city to-day compared to what there was when this was first brought up in the New York Academy of Medicine. The education of the laity to him appeared to be easier than the education of the medical profession.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 28, 1906.

First Vice-President, Dr. H. Seymour Houghton, in the Chair.

Notes on the Urine in Early Life.—Dr. Henry Dwight Chapin read this paper. He first presented and described a urinal which enabled one to collect the urine of male and female babies. He also showed a photograph of the urinal in position. He said he had hoped to be able to collect the full twenty-four-hour amount of urine in babies for the purpose of studying questions relating to metabolism; he was unable to do this because of slight unavoidable leakage in the apparatus. Heretofore the urine of babies had not been studied in a routine way. Dr. Chapin said that the kidneys functionated before birth, and that the kidneys were relatively of larger size and more lobulated than in older life. The kidneys of infants passed a relatively larger amount of urine than adults, and the quantity and composition changed but little. The consensus of opinion was that during the first few days of extrauterine life the infant excreted from one to two ounces a day, and then the quantity increased in amount, as Dr. Chapin showed with figures. The specific gravity was low, averaging 1003 to 1004 during the first few days because urea and salts were not found; the specific gravity was not apt

to rise to 1.010 until after the tenth year. Uric acid crystals might form concretions in the pelvis of the kidney. In proportion to body weight there was less urea in infant's urine than in the child's urine. Infant's urine was neutral, or faintly acid. The question of the presence of pathological ingredients was interesting. Some stated that traces of albumin and hyaline casts in the urine in the early days of life were without significance. A slight glycosuria in the early months of life had been reported, especially when sugar was given so freely in the food. When there was gastrointestinal irritation indican was found. All knew of the rapid metabolism and the vulnerability of the kidneys. As the result of investigations carried on in the babies' wards of the Post-Graduate Hospital, Dr. Chapin gave the following figures. In a series of 86 cases in which there was some disturbance of the gastrointestinal tract, such as indigestion, fermentative diarrhea, catarrhal inflammations, and marasmus, albumin was found in 75; casts were present in 37; of the 10 deaths in this series 14 had albumin and 10 had both albumin and casts; in 32 cases examined for indican, it was found present in 22. In a series of 75 cases of pulmonary disease, such as severe bronchitis, pleurisy, and pneumonia, albumin was found in 49; casts in 32; of the 17 deaths, 15 had albumin and 10 both albumen and casts; of 23 cases in which an examination was made for indican, it was found to be present in 10. In a series of 45 cases of general illness other than mentioned above, albumin was found in 31. In 11 cases of cerebrospinal meningitis, heavy traces of albumin and casts were noted in 9. In a number of cases of cerebrospinal meningitis with coma, where an effort was made to collect the twenty-four hours urine, there was a slight variance between 1.7 per cent. and 2.7 per cent. Dr. Chapin asked what significance could be placed to this. Did it really mean that there was actual renal disease present? Or was there some irritation of the renal tubules? From the cases reported he rather favored the latter view. He concluded his paper by saying that infant's urine could contain traces of albumin and casts without grave results.

The Significance of Albumin and Casts in the Urine of Children.—Dr. Frederic E. Sondern read this paper. He said that in children, even more so than in adults, the occurrence of albumin in the urine, alone or associated with casts, was not the absolute indication of a nephritis once believed, as we knew that its presence did not necessarily indicate an inflammatory lesion of the kidney. The occurrence of a so-called physiological albuminuria was open to question. On the other hand, not only an inflammation of the renal parenchyma in its broadest sense, but also comparatively slight disturbances in circulation, innervation, or in the quality of blood offered the kidney for the exercise of its function, occasioned the passage of smaller or larger amounts of albumin in the urine, with or without casts. The amount of albumin and the number of casts, while possibly significant at times in estimating the acuteness in a given case of nephritis when comparing repeated examinations, were no guide to the severity of the lesion in general. Modern research had demonstrated that a knowledge of the daily excretion of solids or of urea was not an accurate basis for an opinion on the severity of the renal lesion. It was well to keep in mind the normal urea excretion figures: Children 3 to 6 years, 1 gram per kilo body weight; 8 to 11 years, 0.7 gram per kilo body weight; 13 to 16 years, 0.3-0.5 gram per kilo body weight. The changes in a given case on the same diet should be noted. Kreidl and Mandl concluded that under normal conditions the fetus excreted no urine, but on impairment of the excretory ability of the mother the fetus made efforts to clear the blood by renal action. The class of cases in which the albuminuria, with or without casts, was due to functional and not inflammatory renal disorder formed an interesting subject for consideration. While the excretion of albumin seemed to be directly due to changes in the circulation, in the innervation, or in the composition of the blood offered the kidney for the exercise of its function, without appreciable kidney lesion, it seemed a misnomer to call this physiological albuminuria, as in the majority of the instances there was a fault elsewhere if not in the kidney, and the term functional albuminuria, as distinguished from albuminuria of nephritis, would seem more appropriate. In the differentiation between functional and nephritic albuminuria the mere consideration of albumin and casts was not sufficient. The albuminuria, with or without casts, associated with the different types of anemia without circulatory disturbances and due to the changed condition of the blood only, or to a possible toxin, was often most confusing. The demonstration that acute autointoxication, intestinal toxemia, or faulty metabolism was not only the cause of a distinct train of symptoms and frequently explained otherwise obscure manifestations, but was also the direct instigation of a long-continued functional albuminuria, with or without casts, often difficult to differentiate from a true nephritis, was a recognized fact. When it was recalled with what facility disturbances of the gastrointestinal tract were occasioned in the young, and mindful of the fact that intestinal toxemia was particularly prone to cause complicating disorders in them, the necessity for early diagnosis of this condition was evident. The laboratory aid in the detection of intestinal toxemia was important. Albuminuria implied the presence of serum albumin in the urine, and the occurrence of other albumins should not be called by the same name to avoid confusion.

The Urine in Some of the Specific Infectious Diseases.—Dr. Floyd M. Crandall read this paper. The frequency or severity of kidney complications were not in proportion to the gravity of the infection. Such complications, while rare in chickenpox, German measles, whooping-cough, and mumps, were equally rare in measles and smallpox. The frequency of nephritis in diphtheria and scarlet fever must be due to some particular quality in the toxins, and not to the fact that they were among the more severe of the infectious diseases. In parotitis, pertussis, varicella, and rubella albuminuria was not infrequent in the more severe cases. The *late* occurrence of nephritis was peculiar to all the infectious diseases. His own experience would show that nephritis and albuminuria were less common in German measles than in mumps, whooping-cough, or chickenpox. Albumin and a few hyaline casts might occasionally be found in these diseases, but nephritis was rare. In practice it should not be forgotten, however, that in the more serious cases nephritis of grave type was possible, and might prove a serious complication. In measles nephritis was extremely rare, either as a complication or a sequel. In smallpox it was agreed that albumin might be found in a considerable proportion of the confluent cases, but a true nephritis was exceedingly rare. In diphtheria albumin appeared in the majority of the cases, even the mildest, and it could be said that it always appeared in the severe cases. Diphtheria was sometimes ushered in with complete suppression of urine. The nephritis of diphtheria, unlike that of scarlet fever, was rarely marked by edema or general dropsy, and the classical symptoms of uremia were far less common than in scarlet fever. During the febrile stage of scarlet fever traces of albumin were found in all of the more severe cases, and frequently hyaline casts. This was a febrile albuminuria, due to degenerative nephritis, and subsided as the temperature fell. It was not accompanied by dropsy or by suppression. A true kidney complication might occur during the first stage; in grave, septic cases of scarlet fever the urinary findings of the first few days should not be disregarded. The most characteristic and common kidney lesion in scarlet fever was post-scarlatinal nephritis, which was a true diffuse nephritis, and developed most frequently during the third week, but often occurred in the fourth, and was sometimes delayed until the sixth week. The first symptom to be noticed was edema of the face, which was usually

accompanied by feverishness and restlessness. Dropsy and all the characteristics of acute nephritis rapidly developed. The faintest appearance of albumin after the second week of scarlet fever should be a warning of danger. Daily examination of the urine was very important. He was convinced that there was much truth in the statement that one could do more to prevent the occurrence of nephritis by care and proper diet than by any other means at command. Dr. Crandall always kept scarlet fever patients in bed for twenty days, no matter how mild the attack, and did not sanction leaving the bed for at least a week after the fever had subsided. Patients who had developed nephritis should not only be kept under observation until every symptom had disappeared, but for several years thereafter they should receive special care as regarded diet, clothing, exercise, and the urine should be occasionally examined. In closing, he said that even in the mildest infectious disease the occurrence of septic conditions of any kind should be a warning sign and the kidneys should be watched with special care.

The Urine of Pregnancy.—Dr. J. CLIFTON EDGAR asked, what did the study of the urine of pregnancy offer? Had it any decided value? He believed that such a study had a certain diagnostic value, and that such study pointed the way to the prognosis and treatment. During pregnancy urinalysis enabled one to determine that the urine was nontoxic in character; that a given case of persistent vomiting was toxemic in character; that a patient was in the preeclamptic state of the toxemic or nephritic variety; that a given eclampsia was nephritic or toxemic; and, finally, that after delivery it was possible to forecast the tardy or prompt recovery from a toxemia or nephritic condition. Possibly, moreover, urinalysis enabled one to determine the presence of a complex disturbance or toxemia, namely, where the symptoms of toxemia due to faulty metabolism and those due to nephritis were combined. Nine months ago he presented to the Society a paper on "Clinical Manifestations of the Toxemia of Pregnancy" (see MEDICAL RECORD, Vol. LXIX, page 809), a study of 62 complete urinalyses on 24 patients. To-day he could add to this number, making 86 in all, and his conclusions to-day, while somewhat modified, were practically those of nine months ago. Normal pregnancy urine should not be persistently small in quantity, the urea output should not be persistently low, and it should not contain albumin, casts, or excessive quantities of indican. Moreover, the total nitrogen should be represented by proper proportions of the nitrogen compounds. The presence of serum albumin, especially when accompanied by casts, had a greater significance for him in the pregnant than in the nonpregnant state. The belittling of the importance of albumin and casts in the urine of pregnant women had cost many valuable lives. They had two, possibly threefold significance. (1) They might be the only diagnostic sign of the presence of a defective kidney condition, a chronic or an incipient nephritis, a danger signal that the preeclamptic state was already upon them, or that eclampsia was already imminent. (2) They might be the result of a pregnancy toxemia, as indicated by a faulty urinary excretion of nitrogen; the nephritic condition appeared to be the result, and not the cause of the toxemia. (3) Possibly large quantities of indican in the urine might result in nephritic changes and the appearance of albumin and casts; the nephritic condition might be the result, and not the cause of the intestinal intoxication. His observations did not lead him to attach much importance to the presence of an acid or an intestinal intoxication as causative factors in the production of pernicious vomiting or coma. Another urinary sign of diagnostic value was the relation of the nitrogen of the nitrogenous compounds in the urine to the total nitrogen. The persistent vomiting of pregnancy was with few, if any, exceptions toxemic in character, as shown by faulty urinary excretion of nitrogen. Clinically, he distinguished two varieties of preeclamptic states, one largely toxic in character, the other nephritic. Either of these might result in eclampsia with nothing clinically to distinguish them, except that the nephritic yielded more readily to treatment and gave a better prognosis.

Dr. HARLOW BROOKS confessed that, like many others, he knew very little regarding the urine in children and infants, and then called attention to the discrepancies in the findings of albumin in the urine. One should not make a diagnosis of renal disease simply because of the presence of albumin in the urine; and, too, the total absence of urinary findings should not exclude the presence of serious renal disease. At autopsy many cases had been noted of marked renal disease which gave no evidences during life. He had seen several such cases, even where the urine had been carefully examined day after day, failing to find anything abnormal, yet the patient died from renal disease. While all recognized the enormous value of urinary examinations, and the significance of certain foreign bodies in the urine, one should not forget that the absence of abnormalities in the urine did not exclude the possibility of the presence of serious renal disease.

Dr. HENRY KOPLIK said that it was a fact that general practitioners examined the urine more carefully and more frequently than they did formerly. As his diligence increased, so did his responsibility towards his patients; the public expected more from him than the mere report of the presence or absence of albumin and casts. It was undoubtedly true that grave insults to the kidneys could be recovered from with marvelous celerity. Again, all had met with cases in which a nephritis developed quietly, and still no severe etiological factor could be determined. One cannot always trace the peculiar infectious element in the case. Dr. Crandall had sounded a warning in regard to cases following infectious diseases, especially scarlet fever. Leaving scarlet fever out of the question, there was no doubt but that sometimes a perfectly normal kidney would not respond and recover from repeated insults; apparently slight infectious cases might develop a nephritis later in life. When one found albumin and casts in the urine of children and infants, even in those cases that clear up, every opportunity should be given for observation; one should never forget to examine the urine repeatedly in these cases to learn if they have made a permanent recovery. Dr. Sondern had called attention to a form of albuminuria occurring in childhood, and he was candid enough to say that sometimes it was impossible to say whether there was a nephritis present or not. These were the cases that should never be lost sight of. He did not think they should be too optimistic in this matter, yet they should by no means overestimate importance of the occasional appearance of albumin and casts temporarily appearing in infectious or intestinal intoxications.

Dr. FREDERIC E. SONDERN, discussing Dr. Edgar's paper on the urine in pregnancy, said that the great trouble encountered in doing a complete nitrogen partition test was the immense amount of work required. It was a tremendous undertaking to get the total nitrogen, the urea nitrogen, the ammonia nitrogen, the nitrogen of other types, and the undetermined nitrogen. It was a time-consuming operation, and it was not feasible to make these tests every few days in every case. It might take three men an entire day to make one determination, if it was done properly. Every time there was faulty nitrogen partition, invariably there was a diminution in the urea nitrogen. As a routine matter, it might be well to get the total nitrogen and urea nitrogen; then, if the urea nitrogen was depressed one could go ahead and determine which of the other nitrogens were increased. Of chief importance was to find if the urea nitrogen was depressed comparing this with the total nitrogen. The persistent vomiting and other symptoms he did not believe to be due to excess of ammonia. In diabetes, where the urine often contained from 15 per cent., and often 20 per cent. ammonia nitrogen, there was not a sign or symptom that looked like

nausea or vomiting. Therefore, he believed that the persistent vomiting was not caused by an excess of ammonia, but due to that which accompanied it, the toxins, and it was these which did the damage.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held November 20, 1906.

DR. W. F. CAMPBELL IN THE CHAIR.

The Medical Treatment of Those Gastric Disorders in Which the Help of the Surgeon Is Often Demanded.—Dr. CHARLES G. STOCKTON of Buffalo read this paper. In the treatment of disease one had to avoid the two extremes, a leaden-footed timidity, and a frenzy for exploitation. There were many diseases for which surgical intervention was advised, which were formerly thought amenable solely to medical measures. Had the pendulum swung too far toward the surgical side? In the treatment of gastric disease it had to be remembered that frequently there was much complaint of the stomach when the latter was actually without pathological change. In these cases it was necessary to remove the reflex disturbing cause. Then there were some of the severest disturbances of gastric function, forms of indigestion really due to an excess of gastric activity. One of the diseases for which surgical intervention was frequently advised was achylia gastrica. This had the following peculiarities: The appetite was good, but the stomach had no digestive activity. In mild cases the bowels were constipated, but in severe cases there was a post-prandial diarrhea and the stools were lienteric. The victims of achylia gastrica were like persons on whom gastroenterostomy had been performed. In the treatment of these cases the speaker recommended small amounts of hydrochloric acid for its stimulating effect on the intestine. Such patients might have the appearance of good health, but they lacked resisting power, like those having a gastroenterostomy. If there was narrowing of the pylorus it was better to drain through the duodenum by means of pyloropexy rather than to perform a gastroenterostomy. Some of these cases that had lasted from ten to fifteen years responded to medical treatment. Such was true of pylorospasm and extreme dilatation. One of the speaker's cases, that of ulcer of the pylorus, had occurred eighteen years ago, responded to medical treatment, and had no recurrence. Medical treatment served to put certain patients in good condition for operation; as a result some of these frequently felt so well that no operation was necessary, or the operation was deferred. With peptic ulcer at the pylorus or in the duodenum operation was advised. There was less danger from early operation. In ulcer, diet was to be liquid or pultaceous, meals were to be given frequently; bismuth suspended in mucilage was to be administered, and gastric lavage with water containing resorcin was frequently of value. The speaker had found good results from the administration of ichthyol in two or three-drop doses, and iodoform in doses of one-half to one grain. If hyperchlorhydria was present, occasionally a poultice gave comfort, and sometimes ice water. Of late years the speaker had used the stomach tube. In hemorrhage from the stomach he had good results from the use of the stomach tube; the stomach was irrigated with a weak solution of adrenalin one-half a teaspoonful of the 1 to 1,000 solution added to a glassful of tepid water; the later irrigation was by means of a solution of an equal quality of adrenalin to a quart of water. Recently Ewald had recommended ice water or gelatine water. It was necessary to educate all these patients to be content with long-continued treatment. For perforation it was imperative to operate. For shock due to perforation the drug to be used was morphine. This relieved pain, but at the same time it produced an unwillingness on the part of the patient to permit operation. Hemorrhage was also checked by morphine. Complete rest in bed was necessary. Recurrence of hemorrhage could be caused by introduction of large saline enemata. Careful rectal alimentation was indicated. In exploration for hemorrhage at the pylorus or into the duodenum it was frequently found that the oozing came from a turgescent gastric mucosa. Dilatation of the stomach second to atony did not indicate operation. Frequently the condition was one of ptosis and not of dilatation. The measures of treatment included an improvement of the general health, electricity, hot and cold needle baths, cold affusions, and attention to the psychology of dietetics. The diet had to be selected to suit the individual patient. In cardiospasm temporary benefit was obtained from emptying the sac and passing an electrode through the opening. Perigastritis came from other causes than inflammation of the gall-bladder. The pylorus was often the seat of inflammation, of a true perigastritis. For this it was necessary to employ rest, careful diet, and hydrotherapy. For cancer the medical treatment was only palliative.

Certain Surgical Aspects of Chronic Gastric Diseases.—Dr. JAMES G. MUMFORD of Boston, Mass., read this paper. He said that the facts were well known. He confined his remarks to only a few of the conditions of gastric disease for which surgeons operated. Surgeons had struggled for many years against the opposition of conservatives and their work had already borne fruit. Technique had been perfected. It was surprising how little one knew before the stomach was opened. The profession at large, however, was not impressed with the advantages of surgical interference in gastric disease. He usually shrugged his shoulders when gastroenterostomy was suggested for chronic dyspepsia. There was a multitude of cases of long standing that presented themselves to general practitioners, cases presenting symptoms of pain, nausea, heartburn, etc.; among these cases there were certainly some that would be benefited by surgical interference. It had to be remembered that some cases of distress after eating, with gastric pain, might be due to gallstones. He cited a case that had come under his care seventeen years ago. It was that of a young house physician of a Brooklyn hospital, suffering from neurasthenia, and who experienced heartburn, flatulence, and distress in the epigastrium. He had been advised to go away for a long rest. He went to Boston, but did not improve. Shortly afterward, while in a general hospital, he showed sudden collapse, due to the perforation of a duodenal ulcer, as subsequent operation showed. At that time there was little known about duodenal ulcer, but it was evident that the gastric symptoms of which this patient had complained had been due to the adhesions about the duodenum. The ulcer had set up a localized peritonitis. In such cases drainage of the stomach might obviate a long period of invalidism. Another case cited was that of a lady who had suffered from dyspepsia for twenty years. After partaking of food she had experienced pain and tenderness in the hypchondrium. Hysteria was one of the diagnoses that had been made. An exploratory operation revealed the stomach attached to the transverse colon. There was a deep cicatricial infolding of the anterior wall of the stomach, which was of the characteristic hour-glass type. The deformity was similar to that seen in cases of pyloric obstruction. The patient was supposed to have had a peptic ulcer, of which she had manifested symptoms during pregnancy twenty-one years before. The speaker next alluded to the fact that gastric stasis was more common and more intractable than usually recognized. He cited the case of a lady aged thirty-five who had suffered from pain after eating, nausea, and vomiting. There was no hematemesis and the patient lived solely on peptonized milk. A diagnosis of pyloric stenosis was made. Upon operation nothing abnormal was found, but an anastomosis was made with the intestine to insure free drainage. The operation was followed by a careful supervision of the diet for at least one year. She was cured. The speaker next discussed the question whether

the presence of a pyloric tumor in this class of cases contraindicated operation. This he answered in the negative. Moreover, small tumors of the pylorus could be removed. Of course, in the cases of simple gastric atony the objection could be legitimately urged that the patient was exposed to danger in an exploratory laparotomy. But after many of these operations it was possible to get the patient out of bed as early as the fourth day. Moreover, long-continued dyspepsia due to gastric ulcer was frequently the cause of malignant disease.

Stated Meeting, Held December 18, 1906.

DR. W. F. CAMPBELL IN THE CHAIR.

Compulsory Vaccination and Anti-Vaccination.—Dr. GEORGE DOCK of Ann Arbor, Mich., read this paper. He referred to the fact that there was no branch of preventive medicine that exceeded in importance the subject of vaccination. In 1890 occurred the first case at law against compulsory vaccination, and since that time litigation was on the increase. During the past eight years there was an epidemic of smallpox. The present laws were not satisfactory, inasmuch as they were not backed up by public opinion. Even those who admitted the right of the State to enact sumptuary laws regulating the use of tobacco and alcohol frequently disputed its right to inoculate healthy individuals with the virus of cowpox. The prevailing methods of public vaccination were eminently unsatisfactory. There was no definite record of vaccinations. Individuals sometimes washed the virus out of the wounds. In lieu of the present haphazard methods of public vaccination the speaker recommended an organized scientific procedure, having the support of the people. The anti-vaccinationists were troublesome. Recruited notably from intelligent ranks, their arguments were only too sadly fortified by the untoward results in their own personal experience from the use of impure virus. It was necessary to consider better methods of vaccination. The country was now in the latest stages of the smallpox epidemic that began shortly after the Spanish-American War. There was no guarantee, however, that there might not be a sudden recrudescence in the near future. The decline in the epidemic did not signify that the disease had been stamped out. The view had been advanced that the mild character of the recent epidemic was due to the fact that the public had inherited a certain immunity. This view was not proved. In Cleveland, in 1901, the mortality was 1.6 per cent. In 1902 it jumped to 17 per cent., although there were the same number of cases. The mild type was probably due to causes separable from immunity. It was to be expected that a country that was indifferent to the huge mortality from typhoid and from accidental causes would not be very much concerned about the comparatively few deaths from smallpox. It was a scandalous condition that permitted the lawlessness, the shotguns, the wrecking of houses, that frequently occurred when smallpox broke out in a community. If to this were added the unfit pesthouses, the special physicians, the guards, and other requisites, one could conceive the economic disadvantages of even a few cases of smallpox. Moreover, in the presence of such crises, vaccination was performed hurriedly and inefficiently. The experience of Germany furnished the best argument in favor of organized vaccination. Statistics showed that smallpox was always more prevalent in Austria and Russia than in Germany, which also showed a much lower mortality in proportion to its population than in this country. When smallpox was raging throughout Europe the German Army was but little affected by the disease. This was undoubtedly due to the careful performance and supervision of vaccination. The German law compelled vaccination before the second year, again at twelve years, and again all recruits, that is, all males between eighteen and twenty years of age, had to be revaccinated. In Germany general vaccination had created such a sense of security that some cases of smallpox were treated in houses, and some in general hospitals, even in the same wards with other patients, without the disease spreading beyond the first cases. It was noteworthy that the worst systems of public vaccination prevailed in the countries that spoke Jenner's language. A recent investigation of patients in his wards in Michigan showed that of 2,000 individuals only 60 per cent. had been vaccinated, and of these the majority of scars were unsatisfactory. In 1905 one-third of all his hospital cases had been unsatisfactorily vaccinated. Voluntary vaccination as a public safeguard was not satisfactory. In New York and Chicago the public school regulations certainly insured a thoroughly general vaccination, but this was not true of the greater part of the country. It was difficult to decide whether vaccination should be subject to police regulation or should become a part of Federal law. It might not have been necessary to do away with State rights in order to insure perfect vaccination. This latter necessitated not only the vaccination of all individuals at stated periods, but also their registration in public archives; the supervision of all vaccinated cases so as to determine whether the inoculation was successful or not; the maintenance of public stations for the preparation of aseptic vaccine; and the training of physicians competent to perform and recognize the successful outcome of proper vaccination.

CHICAGO MEDICAL SOCIETY.

AT a meeting held January 16, 1907, Dr. A. P. Ohlmacher of Detroit, Michigan, by invitation, detailed a series of medical and surgical affections treated by artificial autoinoculation according to Wright's theory of opsonins. He reviewed Wright's theory of opsonins and spoke of the beneficial therapeutic effects of proper doses of the "corresponding" bacterial vaccine, or of the autogenous one prepared from the patient's own lesion. But less importance was attached to the theory than to the practice of artificial bacterial inoculation as a therapeutic procedure, which the author regarded as Wright's great gift to medical science and to humanity, for Wright has shown how practically all subacute and chronic diseases caused by the pyogenic bacteria, and luckily, too, the tubercle bacillus, could be improved and brought to recovery by small, infrequent doses of the corresponding bacteria. The author's personal experience in the clinical application of Wright's principles included a series of cases of obstinate, intractable, or even incurable affections in which the results have been most surprising, and, judged by any other therapeutic standard, entirely beyond the ordinary range of possibility. Among staphylococcic affections were included examples of chronic acne, both vulgaris and rosacea, subacute and chronic furunculosis, both localized and generalized, axillary adenitis, palmar abscess, impetigo, and a very remarkable case of so-called "rose psoriasis," but what actually proved to be an extensive staphylococcic dermatosis due to the *Staphylococcus aureus*. In all of these cases progressive improvement and ultimate recovery had been the rule, together with splendid gain in appetite, weight, and spirits. A case of colon bacillus pyuria, cystitis, and pyelonephrosis with profound sepsis had been apparently permanently cured by five injections of the autogenous bacterium. Pneumococcus empyema by intercostal puncture and small drainage was brought to a complete recovery in seven days with two injections of the pneumococcic vaccine. A case of genitourinary tuberculosis with tubercle bacilli and pneumococci in the urinary pus had been progressively improving during the five successive injections of a mixed tuberculin and pneumococcic vaccine. With subacute and chronic gonorrheal infections, Dr. Ohlmacher's work began last August, and he had perfected a vaccine from one of several strains of gonococcus which appeared to be of wide therapeutic usefulness. The results obtained in such conditions as balanoposthitis, epididymitis, proctitis, ophthal-

mia, conjunctivitis, vaginitis, and gleet had been most gratifying and unparalleled by any previously established mode of treatment. This consideration applied also to gonorrheal arthritis (gonorrheal rheumatism), in which the specific and highly potent effect of the gonococcus preparation was demonstrated by the immediate and steady improvement of the local and constitutional conditions. In these gonorrheal infections the same gain in tone, weight, and spirits as evidenced in staphylococcic diseases was marked. The address concluded with the statement that in these artificial bacterial inoculations we possessed therapeutic agents of a specificity and potency exceeding anything heretofore employed in the treatment of disease, except possibly the antitoxin of diphtheria.

College of Physicians of Philadelphia: Section on General Medicine.

At a stated meeting held December 10 Dr. Joseph Sailer presented a patient with "Probable Congenital Disease of the Heart." The condition occurred in a girl, fourteen years old, in whom it was known that some disease of the heart had existed from the age of six years. On palpation a marked thrill could be felt in the pulmonic area, while on auscultation a loud, rumbling murmur, continuous throughout both systole and diastole, was audible and transmitted into the carotid arteries. There was neither cyanosis nor clubbing of the finger ends. The lesion was thought to be a persistent ductus arteriosus or pulmonary obstruction. Dr. David Riesman read a paper entitled "Preicteric Itching," and he reported three illustrative cases. The condition was first described by the great Irish physician, Graves. In some instances it disappears when jaundice sets in, so that it must be concluded that it is not due to biliary pigment. It has been observed in cases of benign and malignant disease alike. Dr. Riesman also presented a communication entitled "The Development of Cardiac Murmurs During Attacks of Biliary Colic." He reported several cases in which heart murmurs developed during attacks of biliary colic in persons previously known to be free from such murmurs and disappearing with the termination of the attack. The manifestation must be considered as due to different causes, in some instances to anemia or other change in the blood related to the attendant jaundice, in other instances to dilatation of the heart. Dr. David L. Edsall presented a communication entitled "Further Observations on Metabolism in Purpura." He was able to confirm observations previously recorded to the effect that loss in nitrogen occurs in cases of hemorrhagic purpura, indicating that the affection must be attributed to a toxic state and the resulting blood destruction. Dr. A. P. Francine read a paper entitled "A Review of the Therapeutic Use of Koch's Tuberculin." Reports in the literature would seem to show that, employed cautiously and intelligently in properly selected cases, treatment of tuberculosis with tuberculin yields more favorable results than other methods of treatment. The patients should be free from fever and the doses used should be almost infinitesimal. Reaction should, so far as possible, be avoided, and, of course, all recognized hygienic and nutritive measures should be observed. Tuberculin has further great diagnostic value. Dr. Robert N. Willson read a paper entitled "The Pathogenesis and Treatment of Neurasthenia in the Young." He maintained that neurasthenia is due to impairment of tissue nutrition, and that any mode of treatment, to be successful, must be aimed at improvement in this direction. Often profound inertia on the part of the patient has to be overcome and the utmost personal effort on the part of the physician will be required. No case need be considered helpless, but the treatment must be determined for the individual case, and it should be carried on with unremitting persistence.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 2, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	354	206
Diphtheria	315	46
Measles	138	5
Scarlet Fever	325	15
Smallpox	1	1
Varicella	122	—
Typhoid Fever	35	9
Whooping Cough	75	13
Cerebrospinal Meningitis	20	17
Malarial Fever	....	....
Totals	1385	312

Appendicitis in Nurslings.—Kirmisson and Guimbellot have been able to collect twenty-three cases of this nature. Nine of these were observed in the first year, fourteen in the second year. There were sixteen deaths and seven recoveries. The patients who recovered were all over eighteen months old. Surgical intervention was practised in ten cases, once on a patient in the first year and nine times on patients in the second year with seven recoveries and three deaths. The writers believe that appendicitis in the first years of life is not as rare as is generally thought. Its evolution is rapid, its prognosis extremely grave. Diagnosis is difficult. It would be of interest to have all the facts relating to these cases, which have been observed, collected and published.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 4, 1906.

SUPERNUMERARY CERVICAL RIBS AND THEIR EFFECTS ON THE BRACHIAL PLEXUS AND SUBCLAVIAN ARTERY.*

By COLIN K. RUSSEL, M.D.,

MONTREAL.

CLINICAL ASSISTANT IN NEUROLOGY; CLINICAL ASSISTANT IN MEDICINE, ROYAL VICTORIA HOSPITAL.

CERVICAL ribs are not particularly uncommon and have frequently been demonstrated at autopsy and in the dissecting room,[1] but the clinical symptoms which may be caused by the pressure of supernumerary cervical ribs on the cervical plexus have been given little attention. Thomas and Cushing,[2] in 1903, reported one case and Thorburn,[3] in 1904, published a series of four cases with their clinical histories in which there were definite signs of pressure on the plexus. In Thomas's case, and in two of Thorburn's, the symptoms were particularly well marked, consisting essentially in paralysis of the intrinsic muscles of the hand with pain and some sensory loss about the region of distribution of the first dorsal root. In these three cases the offending rib was removed with relief of the pain, and in Thorburn's case reestablishment of the functions of the paralyzed muscles.

Previous to this Tillman[5] reported the case of a woman, aged forty-four, with a cervical rib on the left side, causing atrophy of the muscles of the ball of the thumb and pains from the neck down the arm, but in this case no loss of sensibility was found. The case was operated on by Bardeleben. Two other cases were operated on in von Bergmann's[4] and three others in Hoffa's clinic, where there was said to be pressure on the plexus but the only symptom reported was pain in the arm.

These are the only reported cases that I have found in a fairly thorough revision of the literature. More or less complete occlusion of the subclavian artery, on the other hand, seems to be more common. Tillman in his revision of the literature collected twenty-six cases, in thirteen of which the presence of the rib caused symptoms; in the other thirteen it was found accidentally. In ten of these cases the symptoms disappeared under symptomatic treatment; three only were operated on (Coate,[7] Fischer,[8] Planet[7]) and all successfully. Babcock[9] of Philadelphia and Murphy[10] of Chicago have also recently published cases in which operation was successful in removing the symptoms.

The following cases will, I think, be of general interest. It is interesting to note also that these patients are brother and sister:

CASE I.—Miss B., aged twenty-seven, nurse, was seen for Dr. Martin on the 24th of April, 1906. *Complaints:* Pain and cramp in the right hand and arm; wasting of the thumb muscles, and general weakness of the right hand.

Present Illness: Started five or six years ago with the sensation of pins and needles in the ulnar side of the right forearm and hand, especially when she was exposed to cold. At the same time she often had cramps in the little and ring fingers of the same hand with flexion of these fingers. Weakness and cramps in the thumb muscles when grasping objects was next noticed, always worse in very cold or very hot weather. About three years ago the definite wasting in the small thumb muscles was first noticed, and at this time she complained of frequent cramps in the hand with flexion of the fingers and wrist. The right hand is always colder than the left, but no change of color has been noticed. These symptoms have been gradually progressive till the present time.

Personal History: Patient has always led a rather active out-of-door life and enjoyed very good health.

FIG. 1.—Atrophy of small muscles of thumb.

Family History: Nothing similar has been observed in her parents. Her brother, however, has somewhat similar complaints. (See Case II.)

The patient's intelligence and training enabled her to describe her symptoms clearly and to mark out with precision the areas of subjective pain. The pupils were equal and reacted to light and accommodation, and the other cranial nerves normal.

In the right arm there was some wasting of the forearm muscles, chiefly on the flexor and ulnar surfaces, there being a difference of half an inch in the circumference three and a half inches above the radial condyles. The abductor brevis pollicis was entirely atrophied. The adductor pollicis and abductor indices were also much wasted. There was no definite weakness in flexion of the right wrist, extension was also about equal right and left. Flexion of fingers slightly weak. There was very definite weakness in all the movements of the thumb and some relative weakness in separating the fingers and

*Read before Montreal Medico-Chirurgical Society, November 16, 1906.

in extending the distal phalanges when the proximal ones were semiflexed, and definite weakness of the grasp of the right hand as compared with the left. Some fibrillary twitchings were noted in the small muscles of the thumb and in the hypothenar muscles, also in the flexor muscles of the forearm. (See Fig. 1.)

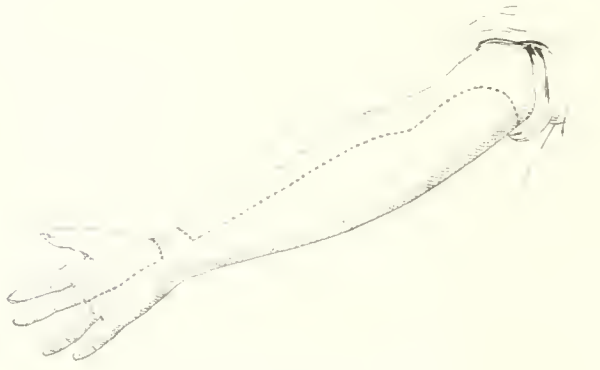

Fig. 2.—Subjective distribution of pain.

Sensory System: The patient complained of sharp aching pain, like toothache, coming on in attacks and radiating down the inside of the arm, quite localized, so that she was able to mark out for me the areas to which it was confined. (See Figs. 2 and 3.) Objectively there was an area of complete anesthesia on the ulnar border of the forearm between the elbow and wrist in the areas supplied by the first dorsal root. (See Figs. 4 and 5.) The reflexes were all normal. There was no spinal curvature. The radial pulse was equal on the two sides and no diminution of the pulse was noted on deep inspiration. The right hand was cooler than the left, but there were no trophic disturbances. The abductor pollicis did not react to either faradic or galvanic stimulation. The flexor brevis and apponens pollicis showed relative diminution in their reactions to faradism.

Skiagraphs showed bilateral supernumerary cervical ribs. (See Fig. 6.)

During the two months before an operation could with convenience be undertaken there was definite though slight increase in the atrophy of the thumb muscles.

The operation for the removal of the rib, performed by Dr. Garrow, has proved so far very successful in that the patient has had no return of the neuralgic pain or of the cramps in the arm. Immediately following the operation, owing to the unavoidable contusion of the nerves, there was increased paralysis of the small muscles of the hand and of the flexor profundus digitorum and flexor carpi ulnaris, with later some increased atrophy of these. There was also an increase in the area of anesthesia and analgesia over the ulnar border of the hand, the little, and the ulnar surfaces of ring fingers. This has, however, all cleared up, and at present, four and a half months after operation, the condition of the muscles is about what it was previous to operation, and the area of loss of sensibility is about one-third smaller than it was at that time. The patient continues perfectly free from the pain and cramps.

Fig. 3.—Subjective distribution of pain.

Case II.—Brother of the preceding patient, clerk, aged thirty-five. *Complaints:* Inability to use the right arm properly; paresthesiæ in hand and forearm.

Present Illness: Nine years ago he had some difficulty in writing; he did not seem able to control his pen properly. Thinking he had gotten into careless habits of writing he tried taking lessons, but in spite of this he did not improve. After writing for some time his hand and forearm felt thick, swollen, and heavy, and he had sensations of pins and needles in the ball of the thumb. It was considered to be writer's cramp and eventually he had to learn to write with his left hand, and since has used either hand, but preferably the left, as he cannot yet control his pen with the right hand for any length of time. Otherwise he has always enjoyed good health.

Fig. 4.—Area of analgesia and anesthesia.

Present Condition: Patient is an intelligent though somewhat neurotic man. The pupils were equal and active to light and accommodation, the other cranial nerves were normal. Apart from some flattening of the thenar eminence in the right hand there was no muscular atrophy. There was some slight relative weakness in abduction, flexion, and opposition of the right thumb as compared with the left. There was no definite weakness in separating the fingers of the right hand.

There was no objective disturbance of sensibility; electrical reactions were all normal; reflexes all normal, and no spinal curvature. Skiagraph shows bilateral supernumerary cervical ribs. (See Fig. 7.)

Case III.—B. P., female, aged twenty-four, sewing girl, came to the medical outdoor department November 8, 1906. *Complaints:* Pain in right shoulder and down inside of arm to hand; cramps of fingers and wrist with flexion. Wasting of small thumb muscles.

Present Illness came on with pain in the shoulder four years ago after a fall in which the patient struck her shoulder. She has had this pain off and on ever since, and lately it has been getting more severe and frequent. It is brought on by allowing her arm to hang by her side or when she wears a heavy overcoat in winter. The pain is not only in the shoulder, but radiates down the inside of the arm to the wrist. She prefers to hold her arm flexed at the elbow in walking, as this prevents the pain.

Fig. 5.—Area of analgesia and anesthesia.

About four months ago she noticed the wasting and weakness of the small muscles of the thumb and first finger of the right hand, and pins and needles sensation in the ball of the thumb, and about three months ago she first had cramps in the hand, with flexion of the fingers and wrist.

Personal History. Otherwise healthy. *Family History:* Negative.

Present Condition: Cranial nerves negative. Pupils equal and react to light and accommodation. *Muscular System:* Wasting of abductor pollicis and indicis of right hand and in the hypothenar muscles, weakness in abduction, and opposition of thumb

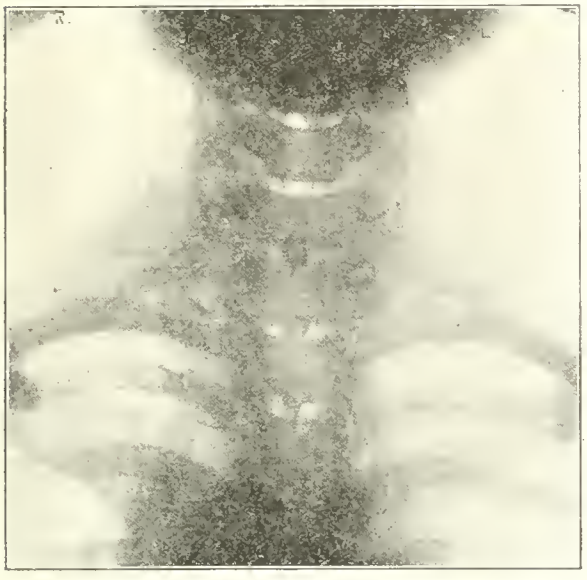

Fig. 6.—Bilateral cervical ribs.

and in the separation of the fingers, especially the first two. *Sensory System:* Apart from the subjective complaints is negative; there is no area of anesthesia nor analgesia to be found anywhere. The reflexes are normal in all extremities, and there is no curvature of the spine.

Her neck is long, with sloping shoulders forming what has been described as the champagne bottle type. There is no difficulty in palpating the ends of the cervical ribs, which are shown by skiagraph Fig. 8.

In Case I the atrophy of the small muscles of the thumb and the weakness of the intrinsic muscles of the hand pointed to involvement of the first dorsal segment, as did also the area of anesthesia and analgesia and the neuralgic pains. The pupils being equal and unaffected placed the lesion distal to the communicating branch of the sympathetic ganglion. Also the fact that her brother was similarly affected rendered it probable that the lesion was not in the cord, but due to some anomaly in the neighborhood of the roots and led to a skiagraph being taken, as in neither case I nor II could we be sure of the presence of the rib by palpation.

Cervical ribs are doubtless a species of atavism and are sometimes found in children of parents who show some stigmata of degeneration. Israel, in his discussion of Borchardt's[12] paper, spoke of having operated on a patient whose sister also had cervical ribs with symptoms, so that heredity seems to be a factor. Doubtless they are often present without causing any symptoms whatever. According to Riesman[11] cervical ribs are more commonly present on the left side, but certainly the symptoms are most often seen in the right arm. They are more frequently met with in women than in men, and first make their appearance between the ages of nineteen and thirty.

It would seem probable then that the more frequent use of the right arm must in some way have an etiological bearing, and the fact that the epiphysis of the head and that of the tubercle of the rib only make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year, would suggest a possible cause of the late development of the symptoms. Certainly in neither of these cases was there any history of previous illness or poor health or loss of weight to bear out Tillman in his contention that this is always a causative factor. In fact the brother has only recently recovered from typhoid fever, and in spite of some loss of weight, etc., shows no increase in his symptoms.

The theory of muscular use and development as a causative factor seems to be borne out in his case. His occupation as clerk involved a great deal of writing, and as soon as he gave up using his right hand altogether and began to use the left there was a diminution in the symptoms.

In our Case I the roots of the brachial plexus were certainly not stretched over the rib as Thorburn suggests as the explanation of his cases. It seems more plausible to suppose that the first dorsal root was pressed on by either the distal end of the rib or its tendinous attachment immediately proximal to its junction with the eighth cervical root, where they unite to form the inner cord of the plexus.

In cases where there is only a slight degree of pressure one may simply find complaints of neuralgic pain radiating down the inner side of the arm, with perhaps some awkwardness in coordinating finer movements of the thumb. Where the pressure is greater it is exerted chiefly on the first dorsal root, causing definite paralysis, with only an irritative condition of the eighth cervical root as shown by the paresthesiæ in the ulnar border of the hand and in the spasmodic cramps of the flexors of the fingers. It seems probable that the center for the flexor profundus digitorum is at the lowest part of the eighth cervical segment, and the cells which subserve flexion of the fourth and fifth fingers have the lowest representation in this center. It is interesting to note that after the operation the flexor carpi

Fig. 7.—Bilateral cervical ribs.

ulnaris was temporarily paralyzed and the area of analgesia extended to what is usually looked upon as the distribution of the sensory fibers of the eighth cervical segment; this, however, only lasted a week or ten days.

The suggestion offered by Case II. of a cervical rib as an organic basis for writer's cramp may be

one of some importance. It certainly has not yet been advanced as an etiological factor of this malady in any of the modern textbooks.

Case IV.—My fourth case differs from the three previous ones. Here, with a certain deformity of the ribs, which may be seen in the skiagram, there was more or less complete occlusion of the subclavian artery. This patient was presented to the society in January, 1906, by Dr. Archibald for diagnosis, he having made the povisional diagnosis of endarteritis obliterans.

M. T., female, aged thirty-one, came to the Royal Victoria Hospital complaining of "burns" on the fingers of the right hand, shooting pains in the right hand and fingers, and numbness in the left index fingers.

Fig. 8.—Cervical ribs.

Present illness commenced about nine years ago with numbness in the fingers of the right hand, accompanied by alternating cyanosis and stone whiteness. For the past year this has increased in severity, and she was advised to put her hand in a solution of carbolic acid, one half ounce to the pint. She admits that she did not stir this up at all, and after using it her fingers became very red, painful, and swollen, and have since become gangrenous. Four years previous to this she came to the hospital with what was probably a cystitis due to gonococcus infection, but did not stay. Otherwise she has always been fairly healthy, though delicate. Has been married nine years.

Her family history is negative.

On admission she was found to be a thin, anemic woman with sloping shoulders. Above the clavicles there was a definite mass on either side of the neck, over which the subclavian arteries could be seen pulsating. The right hand was swollen, tender, and reddened. The superficial layers of the skin were coming off in areas. The tips of the third and fourth fingers were gangrenous. The viscera were normal. Apart from the fact that she was stupid and neurotic the nervous system was normal. Skiagraphs showed what was thought to be undeveloped first thoracic ribs. (Fig. 9.)

In spite of treatment the fingers did not heal. She complained of considerable pain in the fingers preventing her sleeping and also of cold feet, although at no time did her feet become cyanosed. A small area of gangrene now developed on the tip of the index finger of the right hand, and the other fingers and the hand were cyanosed. The index, middle, and ring fingers of the left hand also occasionally became quite cyanosed. The right radial pulse became almost imperceptible and the right brachial was smaller than the left.

On account of the progressive gangrene, in spite of all treatment, it became necessary to amputate first the fingers and later the arm at the level of the insertion of the deltoid. Dr. Klotz found the brachial and radial arteries in the amputated part almost completely obliterated. The vessel showed a proliferation of the inner wall of the vessels and an organized thrombus with formation of canaliculi.

It was at this stage that Dr. Archibald presented the case to the society. In the discussion which fol-

lowed he considered the question of the occlusion of the artery being due to its abnormal course.

On his departure for England in May last, knowing that I was interested in the case, he very kindly asked me to take charge of her. At this time there was very evident involvement of the left hand with alternating blueness and stone-whiteness of the fingers and a small area of commencing gangrene of the ring finger. It was found that when the shoulder was elevated, as by putting the left hand on the right shoulder, the pain in the hand was alleviated. She stated that she always slept with her arm raised under her head, thus elevating the shoulder. Although operation for the removal of the rib was urged the patient would not hear of it. Domestic worries being added to her trouble, she committed suicide on July 7 by taking Paris green. She was taken to the Montreal General Hospital and died next day.

By the kindness of Dr. R. P. Campbell, Superintendent, and Dr. Duval, Pathologist, I was given permission to dissect out the neck on both sides. An autopsy had already been performed by Dr. White, but nothing bearing on the point in question here was found. Vertical incisions were made on both sides of the neck and the vessels and brachial plexus dissected out carefully so as not to disturb their relation to the hard parts more than necessary. The clavicles were then sawed through and the vessels and nerves followed into the axillæ and arms.

On the right side (*i.e.* the side of amputation) the subclavian artery proximal to the thyroid axis was large and soft, but distal to this it was contracted and almost cord-like for a distance of about two and a half inches. In the axilla it widened out again and became more normal looking. In the left side above and below the clavicle the vessel was apparently about normal in size, but underneath the clavicle it was enlarged and on palpation firm and evidently partially thrombosed.

On the left side the upper edge of the vein only could be seen above the level of the clavicle, and below the clavicle there was a huge enlargement and anastomosis of veins over the first space. On both sides the artery extended much higher into the neck than normal. In the second part of its course it lay posteriorly on the scalenus medius, which was attached to this anomalous rib and the second rib, and above the level of this upper rib. It then turned sharply around the scalenus anticus to descend below the clavicle.

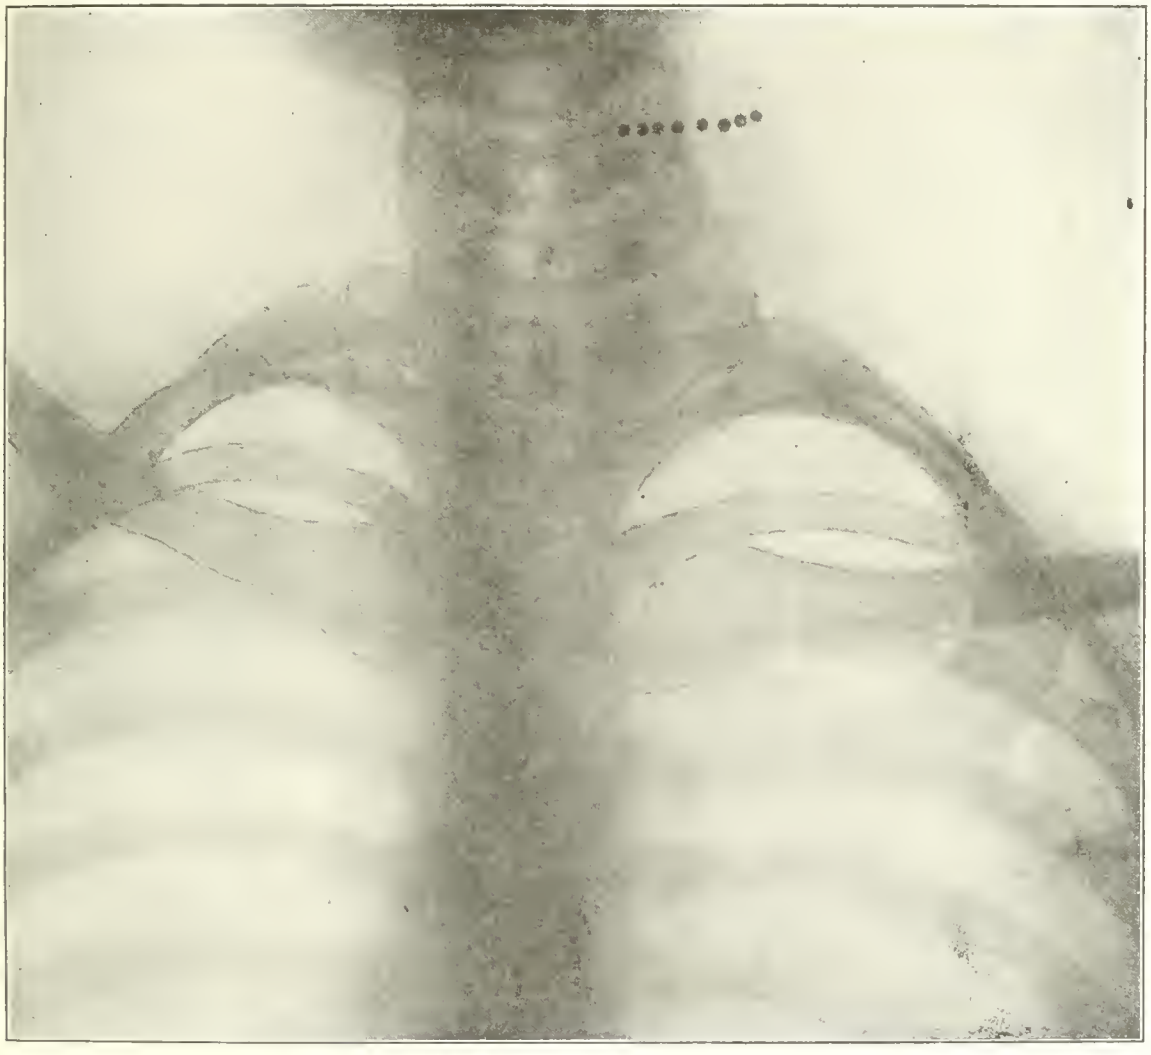

Fig. 9.—Skiagram apparently showing undeveloped cervical ribs.

The first dorsal nerve root ran upward over the ventral surface of the second rib present to join the eighth cervical root which, emerging from between the two ribs just before their junction, formed with it the inner cord of the brachial plexus.

On section, the right subclavian at the level of the thyroid axis showed obliterating endarteritis with an organized thrombus completely blocking the lumen save for a few canaliculi which had formed in the thrombus. The vessel just above the level of the clavicle showed the same condition.

In the axilla the vessel wall showed merely a slight thickening and proliferation of the inner coat. On the left side, at the level of the thyroid axis, the vessel wall showed practically no changes. At the level of the clavicle it was almost completey occluded by an organized thrombus which seemed to have originated and was most advanced on one side of the vessel. In the axilla the vessel was again about normal.

Sections of the radial on the left side and of the posterior tibial on both sides showed no thickening of the vessel walls.

Whether this is really a cervical rib or an undeveloped first thoracic rib remains in my opinion somewhat doubtful. The skiagraphs seem to point to the latter, showing only twelve ribs in all, with apparently only five vertebræ between the last rib-bearing vertebra and the sacrum. On the other hand, the eighth cervical nerve root certainly came out below the first rib present and the first dorsal below the second rib. These joined on the upper anterior edge of the second rib present to form the inner cord of the plexus, and Lane reports cases in which with a cervical rib present the twelfth dorsal rib is very small or absent, merely represented by long transverse processes, and considers that the cause which determines the presence of the cervical ribs also causes a want of development of the lower ribs. Again, in the skiagraph, the first rib articulating with the sternum is flat and broad looking, like a first thoracic rib, although possibly not very much weight can be attached to this point, as in a specimen of Dr. Shepherd's in the McGill Museum showing what is evidently a deformed first thoracic rib, the second thoracic has more or less this character. Certainly on dissection this rib seemed relatively very high above the clavicle. It is possible that here there may have been a fusion of the seventh cervical and first dorsal vertebræ, in this way accounting for the deformity of the rib and the anomalous course of the eighth cervical nerve root.

Whatever its real nature is—and it is to be regretted that owing to the shortness of time at our disposal we could not make it out more clearly—this deformity has evidently been the cause of the thrombosis and occlusion of the artery. The modus operandi seemed to be this: The arch of the vessel ran very high in the neck, being bounded behind by the scalenus medius and the upper border of this anomalous rib, and in front by the scalenus anticus. Its downward and lateral curve was limited laterally by the anterior end of the rib and its junction with the second rib present. Its downward and outward angle, as it dips under the clavicle, increased on account of the relatively low position of this bone. It is here that the greatest obstruction seemed to be present, as shown in the vessel of the left side, where the process is less advanced, although it is probable some obstruction is offered to the blood stream by the sharper turns which the vessel has been compelled to take in the second part of its course, as well, causing slowing of the blood streams, gradual blocking of this, and closing off the thyroid axis and loss of the collateral circulation.

The obliterating endarteritis and organized thrombus which were present in the radial vessels after amputation of the right arm may, I think, be accounted for without supposing that such a condition was a general one. At this time there must have been an almost complete occlusion of the subclavian artery with a maintenance of the blood supply to the extremity through the thyroid axis. This was necessarily insufficient, as the obstruction to the blood stream, if this theory be correct, was exerted on this part of the vessel as well. The blood pressure was consequently very much diminished, and at last, as the thyroid axis itself also became partially occluded, it was only sufficient to maintain the circulation in the proximal parts of the vessels.

The onset of symptoms relatively late in life is probably due to the same causes which produce symptoms of pressure on the plexus at about this same period of life. It is conceivable also that other etiological factors were present, *e.g.* the action of the carbolic acid, or the toxines of the gonococcus circulating in the blood; these points we hope to bring up in another paper in conjunction with Dr. Archibald.

In considering the matter of operation for the removal of the rib, in Babcock's case, which was very similar to this one, having beginning gangrene of the fingers and almost complete obliteration of the radial pulse, removal of the rib restored the circulation and entirely cured the condition. One cannot imagine this interference affecting the thrombosis which had occurred under the clavicle, but it seems more probable the effect was to relieve the condition by maintaining the collateral circulation by way of the thyroid axis and its branches.

THE APPROACHING CONQUEST OF CANCER.

By ROBERT BELL, M.D.,

LONDON, ENGLAND.

WHILE all who are interested in the treatment of cancer will hail with satisfaction and pleasure the record of those gratifying results said to have been obtained by the introduction of trypsin into the blood stream, it would be foolish in the extreme to imagine for a moment that trypsin or any other isolated agent will ever *per se* prove an antidote to cancer. It is not my intention at this time to extol any other method of treatment of this disease, though I am well acquainted with such and have observed many instances in which cancer has not only disappeared but has not recurred for a period of ten years and still shows no tendency to recur-

rence. My object is rather to discuss the rationale of this line of treatment in what I consider to be a fair and unbiased manner.

Dr. Beard, the author of the trypsin treatment of cancer, if I understand him aright, was led to infer from certain experiments that the disease had some connection with a deficient production of trypsin. I say *production* of trypsin, as I think this can hardly be termed a secretion of the pancreas, seeing it may not be present at all in the gland at the time the latter is removed from the body; but when it is allowed to remain exposed to the air for some hours trypsin makes its appearance in considerable quantity. In short, there is a conversion of zymogen into this ferment, and as we know this change takes place in circumstances where it is an impossibility for secretion to be coincident, we are bound to admit that it is a derivative of one of the most important constituents of the pancreatic juice. This fact does not of course detract in the least from its value as a digestive agent, but it points to the conclusion that if cancer is due to the absence or deficiency of trypsin then we must look upon a disabled condition of the pancreas as the primary cause of cancer. To get at the root of the matter, however, we are under the necessity of going further back still to ascertain the cause of this morbid condition of the pancreas. In this way we may possibly arrive at the *fons et origo mali*, and thus be enabled to deal with the disease satisfactorily as a whole and not confine ourselves to the treatment of a symptom which the local manifestation of cancer undoubtedly is. It is this short-sightedness which has been the stumbling block to previous methods of treatment, and will continue to prove fatal to all methods which do not aim at removal of those factors which have been insidiously sapping the integrity of the organs which exert such an important influence upon healthy cell life. It is to this oversight that thousands of painful deaths are annually due, and which will continue to be perpetuated no matter what local treatment be devised, if this does not go hand in hand with dietetic and general measures which hold in view the relief and restoration to health of those organs whose functional activity has been prostrated by the persistent neglect of hygienic laws.

It must be obvious to every observer how miserably surgery has failed to give relief in cancer, and the result has been very much the same, whatever local measures have been adopted, when sole reliance is placed upon them. For example, I have known of cases when the subcutaneous injection of a 1 per cent. solution of caustic potash has had a temporarily marked beneficial effect in epithelioma, and Dr. Webb has reported several cases of breast cancer which have been arrested by the injection of a solution of soap into the tissues; but I have not heard of any permanent relief being obtained by these measures.

It is not my intention to refer in this paper to my own method of dealing with this disease. This has been freely dilated upon on many occasions. What I wish to prevent, if possible, is the booming of a treatment which has not been in existence for anything like a long enough period to place it beyond the experimental stage. The public have had so many disappointments that it would be a pity to add another to the number, and though treatment by trypsin may, and I trust will, prove a valuable adjunct to dietetic and constitutional measures, I fail to apprehend how it can possibly by its sole influence have any permanent effect. Cancer is not a disease, so far as I can judge, due to any one cause, but to a chain of causes and effects made up of many links, each of which requires special attention. Two circumstances have impelled me to communicate my views on this important subject: First, the optimistic articles which have appeared in the lay press, and second, the fact of a lady coming to my consulting rooms who was suffering from recurrence of cancer in the right side after two extensive operations had been performed within one year, and when the condition of the parts was infinitely worse than it would have been had the breast been left alone. Well, this lady had just returned from Edinburgh, where she had been under the trypsin treatment for ten weeks, during which period the other breast had become involved, while the original site of the disease could hardly look worse than it did that day. This, however, being the only case I have seen after this treatment had been employed, I certainly would not condemn it on that account. Indeed, I am convinced there is value in it, as I have stated in my last book on the subject, as an adjunct to other methods which are of proved value—and the manner in which I trust it will prove of immense service is that the ferment by attacking the weaker cells of the morbid growth may destroy them, and thus arrest the local increase of the disease. If this can be accomplished while the healthy condition of the neighboring tissue is improved by judicious measures, an important advance will have been made, because the colony or colonies of malignant cells are thus rendered innocuous and will disappear by absorption. The vitality of the tissues will not therefore be diminished as would be the case if the disease had been removed by the knife.

It would be well, I think, in this connection, to glance for a little at the functional utility of the pancreas, especially in relation to the incidence of cancer. This gland, as we know, is possessed of certain important functions, these being supplementary to those of the salivary glands and the stomach, so that it, as it were, is placed as a sentinel to watch over the contents of the stomach as they escape into the duodenum and complete the process of digestion where it has been deficient. This it will succeed in accomplishing provided the food has not been in excess of the requirements of the body and of such a character as can be efficiently dealt with by the digestive organs. On the other hand, it should be borne in mind that if the blood is in a vitiated state, the pancreas, as well as other important organs, will in consequence have its functional activity seriously reduced, and if this continues indefinitely the organs may possibly be rendered incapable of fulfilling their duties even to a limited extent. If the food is in excess in quantity or contains a superabundance of albuminous material in an indigestible form, such as butcher's meat, then as a matter of course that portion which is not dealt with by the digestive fluids will pass into the intestine as effete matter in a highly decomposable form. There we know it will be liable to undergo fermentation of a most noxious description. Now if this putrid mass is retained in the colon for an undue length of time—and this is invariably the case in persons prone to cancer—absorption of the fluid portion takes place and autotoxemia is the result. The various organs of the body are therefore deprived of their normal pabulum and instead are supplied by a vitiated blood stream. Is it to be wondered at then that they fail to fulfill their important duties? And when it is remembered that the nervous system is necessarily handicapped from

the same cause we can easily conceive to what extent the resisting power to disease of any description is reduced. We are unable, therefore, to look upon trypsin as an antitoxin so far as cancer is concerned, though we are aware that the secretion of the pancreas, like that of the stomach and liver, is antiseptic to a certain extent. This antiseptic, however, is quite incapable of preventing the formation of toxins in the intestine, for the reason that as a rule the quantity of the food consumed is far in excess of the requirements of the body and of a character which the various gastric secretions are quite unable to deal with in a satisfactory manner. It would therefore, I think, be inaccurate if trypsin were described as an antitoxin which I am informed has been suggested. The thyroid gland, on the other hand, possesses decided antitoxic properties which fact has been frequently demonstrated. It was only yesterday I was told by a gentleman a surgeon had said that a motion of the bowels was necessary only once in three days. One can hardly imagine it possible that any intelligent man would countenance so flagrant a contempt of such an important hygienic law as the daily evacuation of the intestinal canal most assuredly is. The very idea of carrying about in one's inside for three days a putrescent mass, which he would not tolerate for three minutes were it in sight, is beyond my comprehension. Depend upon it, it is ignorance regarding this maxim and wanton disobedience to it which constitute the primary factor in disease of all kinds, and in cancer in particular. When, superadded to this, the most flagrant errors in diet are of daily occurrence, the danger is accentuated to a most serious degree. It is to these causes that must be attributed to a great extent the failure of the organs of nutrition and the blood glands to perform in an efficient manner the important duties that have been allotted to them. The result is a departure from the healthy to a morbid condition of cell life in various parts of the body, and we know this morbid tendency appears to be increased at the seat of an injury or prolonged irritation, by which the cellular tissue has been still further weakened. It is in such circumstances that cells which have departed from the normal standard are enabled to assert their depraved individuality and commence a new rôle of existence.

Now the effect trypsin is said to exercise upon these morbidly affected areas goes to prove the correctness of the views advanced by those who for a long period have maintained that a malignant cell is intrinsically weaker than a normal cell. It goes without saying, therefore, that if we can by any means instill an increase of vigor into the latter we shall be enabled to subdue the former, and this is one of the chief objects we should aim at in our endeavor to subjugate cancer. But by far the most desirable object to attain is its prevention, and this I hold is within the grasp of any one who will obey implicitly those laws which nature has so explicitly formulated for our guidance.

The question naturally arises, does trypsin act only on the local manifestation of the disease, and does it exert such a beneficial influence as to reduce the tendency to recurrence of the disease at a more or less remote period? Does it favor cell metabolism to the extent of removing the tendency to revert again to any future manifestation of malignancy either in its previous seat or in any other locality? I fear not, as so far as is known trypsin or any other ferment is incapable of exercising this power. It is then on restoration of the functional activity of the thyroid gland, together with a judicious diet, abundance of fresh air, and careful attention to the hygienic condition of the lower bowel that we must depend for recovery and maintenance of vigorous and healthy cell life. So far we have no grounds for assuming that trypsin is capable of exerting any influence whatever upon cell metabolism, whereas we have the most conclusive evidence to prove that the thyroid gland not only possesses the power of inhibiting the effect of autotoxemia, but also exercises a most potent influence upon healthy cell metabolism. It is therefore of the first importance in the treatment of cancer to aim at restoring the functional activity of this gland and at the same time to adopt measures which will reduce the tendency to the introduction of toxic material from the intestines. Now the latter can only be accomplished by adapting the dietary to the requirements of the body and the capability of the digestive organs to effect complete digestion and assimilation, together with the thorough evacuation of the effete matter at least once in twenty-four hours. By this means the blood will be relieved of an incubus which otherwise would exist, and the various organs be enabled to obtain an uncontaminated blood supply which would enable them to resume their functional activity, and possibly restore their wonted efficiency. That the thyroid has an important relationship to the incidence of cancer is borne out by the fact that in cancer subjects it is invariably found to be more or less atrophied, hence it is necessary to supplement the modified dietetic measures recommended by the administration of either thyroid gland substance or its active principle. By these means we have reason to hope the gland may recover its lost power and thus be enabled to resume its physiological activity, which is quite within the range of possibility.

It must not be inferred, however, that the thyroid is the only organ whose utility is impaired in these circumstances. The salivary glands as a rule become more active, while hydrochloric acid is present in the stomach in very much diminished quantity, if it does not disappear entirely, and it is only reasonable to suppose that the pancreatic secretion is likewise to a certain extent in abeyance from the same cause. In this way we may account for the serious loss of weight which is so prominent a feature in cancer, seeing the digestion must obviously be seriously handicapped, and therefore the products available for assimilation reduced in quantity. And if the proteids have not been converted into peptones, but have passed into the intestines in a condition which favors decomposition and therefore the development of enterotoxins, these, finding their way by absorption into the blood, will assist largely in giving rise to that condition which we term the cancerous cachexia, and as a matter of course will perpetuate the disease process by depriving the various organs of their healthy blood supply and substituting a toxic fluid. It is not the first time that I have sought to draw attention to the importance of this factor as a most potent predisposing cause of cancer, though perhaps not exactly in connection with the treatment of this disease as suggested by Dr. Beard. And I am convinced that no treatment can ever prove successful unless it is removed and not permitted to reassert itself. It matters not what treatment we adopt, even though it may appear to prove of service for a time, if we fail to restore the functional activity of those organs which have been permitted to lapse into an unhealthy condition.

No machine can possibly act efficiently unless all its parts are in good going order. So it is with

the human organism. Doubtless it is capable of submitting to considerable ill-usage with an elasticity which is marvelous, but the breaking strain will assuredly be reached sooner or later, and coincident with it those morbid changes which we term disease, be it malignant or otherwise.

On December 12 Mr. Edmund Owen delivered a lecture at the Royal College of Surgeons on "Cancer, Its Treatment by Modern Means," in which he did not mention any of the modern means even by name. The only method referred to was that of surgery, which everyone knows has seldom given permanent relief and usually succeeds only in aggravating the suffering and shortening the life of the patient. He also spoke in anything but a charitable manner of those who have studied not only the local symptom of the disease—which is all the surgeon takes cognizance of—but the conditions which have led up to this. He would appear to apply the term quack to those who are just as well aware as he is that surgery has proved quite incompetent to deal successfully with cancer, but who have relied upon dietetic and therapeutic measures, and who in consequence have received much more encouraging results than surgery has ever been able to achieve. For my part, I would feel much more inclined to apply the term "quack" to a man who takes a fee for an operation which he knows for a certainty will only result in failure. The surgeon *ought* to be aware of the fact, if he is not, that long prior to the local tangible appearance of the disease the conditions which have permitted this to assert itself were latent in the system and that in the majority of instances a direct injury or prolonged irritation, weakening the part, permitted the disease to proclaim its presence in the enfeebled tissue. How then, may I ask, can it be reasonably expected if no measures are adopted to remove the *casus morbi,* that the greater injury caused by the knife will not have a much more disastrous effect upon the vitality and resisting power of the mutilated tissues, thus inviting recurrence which almost invariably is the sequela.

We have now learned that cancer, as we recognize it, is the culminating point of a series of changes which have taken place, seriatim, in certain important organs, consequent in the first instance upon their being compelled to rely upon a vitiated blood supply, this having been brought about to a great extent by gross negligence of hygienic laws and overindulgence in articles of diet which are unsuitable to our digestive apparatus.

15 Half Moon Street, W.

INTRANASAL CONDITIONS AS BEARING UPON THE ETIOLOGY OF DISEASES OF THE EAR.

By G. HUDSON-MAKUEN, M.D.,

PHILADELPHIA.

PROFESSOR OF DEFECTS OF SPEECH IN THE PHILADELPHIA POLYCLINIC HOSPITAL AND COLLEGE FOR GRADUATES IN MEDICINE; AND LARYNGOLOGIST AND OTOLOGIST TO THE CHESTER HOSPITAL AND TO THE FREDERICK DOUGLASS MEMORIAL HOSPITAL.

It is now nearly twenty years since Wilhelm Meyer first pointed out the close relationship between nasopharyngeal obstructions and diseases of the ear, and his monograph on the subject was epoch making and exhaustive. It called attention for the first time to the interdependence not only of nasopharyngeal and aural diseases, but also of nasopharyngeal and laryngeal diseases; and it served to make clear the utter uselessness and folly of attempting to cure the great majority of diseases of the ear and larynx without at first taking into consideration the conditions in the nose and pharynx. It did as much as any other one thing to divorce the eye and ear in the common practice of specialists, and to join the nasopharynx with both the ear and the larynx.

Formerly we had eye and ear specialists and laryngologists, but no rhinologists. Now a more fitting and comprehensive title, both from an anatomic and pathologic point of view, would be rhinopharyngologists, because the rhinopharynx not only occupies a position midway between the other four important cavities, the nose, mouth, ear, and larynx, but is itself the starting point of many, if not the majority, of the diseases of these cavities.

In the light of recent experience and in these days of preventive medicine, it is to the rhinopharyngologist that we look for the best results, for if we can keep the nasopharynx in good condition and the nasal accessory cavities well drained and ventilated we shall eliminate not only the majority of aural and laryngeal diseases, but also many of the ophthalmic diseases as well.

The purpose of this paper is not to add anything new to the literature of the subject, but to refresh our memories of the things that are old, and to direct attention to a few points of value that have come under my observation bearing upon the relationship between the nose and ear.

That diseases of the ear, especially in their initial stages, are largely dependent upon intranasal conditions, is a fact well known to otologists, but it is not generally recognized by practitioners of medicine. In this connection the following points in the anatomic and physiologic relationship of the ear and nasopharynx can not be too often or too strongly emphasized. The tubotympanum is a cul-de-sac or sinus, occupying exactly the same relation to the nasal cavity that the sphenoid, ethmoid, maxillary and frontal sinuses occupy, and the lining membrane of the tubotympanum is merely a continuation of that which lines the nasal and accessory cavities. Moreover, the physiologic relationship of the middle ear to the nasal cavity is also similar to that of the other sinuses. It has its drainage through the nasopharynx and it is aerated by means of nasopharyngeal respiration. There is a slight excursion of the drum membrane during each respiration, the motion being inward during inspiration and outward during expiration.

The conditions in the nasal cavities giving rise to acute diseases of the ear are, first, those causing disturbances of nasal respiration; second, those attended by suppurative intranasal and sinus inflammation, and third, any condition which by pressure or otherwise may give rise to reflex disturbances. The first class includes hypertrophic and atrophic rhinitis, intranasal growths, septal deflections and spurs, and nasopharyngeal hypertrophies and tumors; and the damage to the ear is chiefly mechanical in its origin. The second class includes all catarrhal conditions of the nasal and accessory cavities, and the damage to the ear is usually by continuity of structure. The third class includes those conditions which give rise to irritation of the terminal nerves in the nasal and accessory cavities and set up ear complications by so-called reflex action.

The tubotympanum is especially liable to damage by mechanical forces acting upon its sensitive and flexible membranes. The air pressure within the normal middle ear being about equal to that in the external auditory canal, and varying only slightly with each respiratory movement, the integrity of the drum membrane is maintained; but, when for

any reason, such as muscular insufficiency, or inflammatory deposition, the Eustachian tube becomes partially or wholly occluded, the air pressure in the middle ear diminishes, and the result is a retraction of the drum membrane and the beginning of a catarrhal process in the tympanum and mastoid cells. This condition may be so insidious in its onset as to be scarcely noticed by the patient, but to those of a sensitive nature there is generally a feeling of fullness in the side of the head. The Germans call this condition a "locked ear." It is often accompanied by tinnitus and dullness of hearing, and sometimes by pain.

The tubotympanum being an offshoot, so to speak, of the nasopharyngeal cavity, the rationale of the development of ear affections from the nasopharynx by continuity of structure is readily recognized, and calls for no special comment.

We now pass to the third class; namely, that in which intranasal conditions produce ear complications by means of reflex nervous action. This part of the subject is none the less interesting because it is somewhat theoretic and problematic. Reflex nervous affections, however, are established facts. Every otologist, for instance, is familiar with the nasal, pharyngeal and laryngeal irritation arising from the use of a probe in the external auditory canal, and, it being a poor rule that will not work both ways, it is not unreasonable to suppose that irritation or pressure upon the sensory nerves of the nasal and accessory cavities will occasion aural disturbances, such as deafness, vertigo and pain.

An interesting and unusual case has come under my own observation. The patient had a slight affection of the septum with an exostosis, impinging upon the inferior turbinal bone at the junction of the posterior with the middle third. The symptoms for many years were of little account, barring an occasional attack of rhinitis when there was some conscious obstruction to nasal respiration, but at about thirty years of age there developed slight tubal symptoms. There were brief sensations of fullness in the ear and occasional vertigo. So trivial had been the nasal symptoms that no connection between them and the aural disturbances was at first suspected, but as the trouble continued it was thought best to correct the nasal irregularity. The spur was removed by my friend and colleague, Dr. Walter J. Freeman; the symptoms at once subsided and have not returned. The above is a report of my own individual experience, and I can, therefore, vouch for its authenticity.

Severe pain in the ear may also be the result of pathologic conditions in the nasal and accessory cavities. Many illustrations of this fact might be given. At the recent meeting of the British Medical Society, in Toronto, Dr. St. Clair Thompson said, that in several of the many cases reported of aural pain due to sphenoidal disease, the mastoid was suspected and even opened before the real cause of the trouble was determined. This one report, it seems to me, emphasizes in a striking manner the importance of this discussion, and the necessity for its frequent revival on occasions of this sort.

The fact that so many diseases of the ear are of nasal origin, however, must not lead us to overlook those that develop in the ear itself, and the fact that such brilliant results are obtained by treatment directed to the nasal cavities must not lead us to underestimate the value of treatment applied directly to the ear. In other words, the otologist should look beyond the ear in all cases of ear disease, and the rhinologist should look beyond the nose when aural symptoms present themselves.

1527 Walnut Street.

STREPTOCOCCUS PNEUMONIA.*

By G. W. McCaskey, M.D.,

Fort Wayne, Ind.

Professor of Medicine and Clinical Medicine, Purdue University; Physician to Home Hospital.

The rôle of the streptococci in general pathology is very important. This is well recognized in surgical practice, but in internal medicine not as much so as it should be. Not long ago I reported in the Cincinnati *Lancet-Clinic* a case of generalized fatal streptococcus infection, probably of intestinal origin, the incidence of the attack being determined by a severe chilling of the body from exposure, just as Pasteur's hen contracted charbon, after being forced to stand with its feet in cold water, by a dose to which it had been immune before the resistance had been lowered by this treatment. The intestinal tube contains streptococci in a large proportion of normal individuals, and I have occasionally found the numbers excessive without any clinical manifestations. Under conditions of a favorable environment, created by altered secretions, constipation, etc., their number may enormously increase, making them, as they were in the case just referred to, the predominating organism. The bacteriolysins of the blood, the phagocytes, and the liver are ordinarily equal to the task of destroying the not inconsiderable number of these and various other microorganisms which run the gauntlet of the intestinal epithelium and enter the portal circulation. With lowered resistance, incidental to fatigue, exposure, etc., this protection may fail and infections occur which may be general in character or secondarily localized in more or less distant areas, or both.

It is thus that abscesses sometimes result from latent foci of infection, their incidence being determined by local disturbances of the circulation from various causes. In one case, for instance, in which I made a diagnosis of brain abscess which was opened and drained, I was able to demonstrate the Eberth bacillus as the pyogenic organism, although the patient had certainly not had typhoid fever for eight or ten years before. This organism, as well as others, may remain innocuous in deep seated tissues for years and set up pathological processes under favorable conditions. Streptococci, however, are very nearly always present in some part of the digestive canal. Several observers have found them, for instance, in the mouth as well as in the intestines.

Streptococcus infection of the lungs is not a very rare occurrence in generalized septic processes occurring in the puerperal state as a result of traumatisms, etc. Such infections are usually localized in character perhaps in the form of an abscess, or may simulate the type of lobular pneumonia. In fact, the clinical investigations of Finkler fully established the occurrence of a type of pneumonia caused by streptococcus infection. Streptococcal bronchitis had already been recognized, but his observations demonstrated clinically and pathologically the occurrence of a cellular inflammation of the lungs decidedly characteristic in type produced by the streptococcus. In no case coming to autopsy was the inflammation croupous in character, showing a definite anatomical distinction between the lesions

*Read by title before the Ohio Valley Medical Association, Louisville, Ky., October, 1906.

of this disease and those of lobar pneumonia. While the anatomical distinction was clearly defined the physical signs were not equally characteristic. In one of his cases, for instance, he says, "Percussion gave dullness over a wide area on the left side below over approximately the lower half of this lobe. Auscultation revealed bronchial breathing with very fine crepitant râles." This would certainly fit a case of genuine lobar pneumonia fairly well. The general clinical course, however, was very erratic, some of the cases showing a subnormal temperature, others at times 103.5°.

If with physical signs, such as those above described, a sharp rise of temperature would occur simulating the initial stage of lobar pneumonia, the distinction between the streptococcal and diplococcal types might be difficult or impossible. Such a temperature curve in some cases of streptococcus infection is familiar to every clinician. In fact, the case referred to at the opening of this article began with a chill and a temperature of 104° or 105°.

Such a case of pneumonia with the characteristic onset and physical signs and clearly due to a streptococcus infection has actually come under my own observation. Following is the case

The patient, Mrs. ——, seen in consultation with Dr. Kithcart, of Columbia City, February 17, 1905, was the mother of four children, the youngest being four months old. Was always healthy until one week prior to my visit, when she was suddenly taken with a chill after exposure during a long drive. She was found by her physician with a temperature of 103°. For two days there was no cough nor râles, although the temperature continued at about 103° to 104°. On the third day crepitant râles were heard in the base gradually extending upward, dullness on percussion only appearing a couple of days later. At the time of my visit the patient was mildly delirious, and had been for about three days. Temperature, 103.5°; pulse, 120. Blood examination showed leucocytosis of 27,300. The examination of the urine revealed both albumin and casts due, as the sequel showed, to transient toxic nephritis. I did not see the patient again, but the course of the disease was favorable, the severe symptoms subsiding by crisis. Two or three days later the temperature suddenly dropped from 102° to 99.8°, and the pulse below 100, remaining so through convalescence, which was uneventful, the lung clearing up completely in about the usual time.

The bronchial secretions were found to be almost a pure streptococcus infection. On the most careful search not a single diplococcus was found, although there were other cocci not arranged in either chains or pairs.

The proof of the streptococcal nature of this case appears to be conclusive, and is, in fact, precisely the same as that upon which Finkler's decision was based in his cases, yet clinically it corresponded very closely to the ordinary type of lobar pneumonia. It not only began with a chill and a sharp initial rise of temperature, but defervescence occurred by crisis. With regard to this latter point, however, a considerable number of cases of lobar pneumonia disappear by lysis instead of crisis, so that crisis cannot be regarded as either essential or pathognomonic of lobar pneumonia. Whatever may be the biochemical explanations of crisis there seems to be no reason why it might not occur with other than diplococcal infections, and it actually did so in this case.

It seems quite probable that if bacteriologic examinations were more frequently made the disease clinically diagnosticated as lobar pneumonia might often be found to be due to other infections. The diplococcus is said by observers to be found in only about seventy-five per cent. of the cases of lobar pneumonia, which raises a very proper question concerning the bacteriology of the remaining twenty-five per cent. It is perhaps possible, although it seems quite improbable, that an active agent in the production of a pneumonia would not be found in the sputum. Netter found the *Diplococcus pneumoniæ* 82 times in 82 autopsies of lobar pneumonia, although other observers have failed to find it with the same uniformity. The possibility of the infecting agent disappearing from the sputum is well illustrated by a case of what was probably a streptococcus infection of the lungs which I recently saw in consultation with Drs. M. V. Replogle and J. U. Riggs, of Bryan, O. There was localized consolidation of the lower lobe of one lung with the indications of general sepsis, and yet the sputum failed to show diplococci or streptococci or any other active pathogenic organism in numbers sufficient to justify the assumption of their causal relationship to the pulmonary process. When I saw the case it was in the twelfth week of a puerperal infection, which a little later proved fatal. In another case which I saw in consultation with Dr. N. T. Dean, of Hicksville, O., the patient had been subjected to a minor surgical procedure which had healed perfectly by first intention, but there was an entirely groundless suspicion on the part of the patient's friends that the pneumonia might have been secondary to a wound infection. I was able at the bedside to demonstrate that the infecting germ was the *Diplococcus pneumoniæ*, which, although sometimes pyogenic, has never, so far as I know, been demonstrated as the agent of wound infection.

As illustrating the erratic manifestations of pneumococcal infections, I might mention another case seen in consultation with Dr. Powell, of Defiance, O., in which the later clinical picture was that of an intense septic infection. When seen by me in the fourth week there had been chills occurring once and sometimes twice a day, followed by high fever (104°) and profuse perspiration, the temperature preceding the chill being usually close to normal. There was a leucocytosis of 28,000. Notwithstanding this picture the sputum was very nearly a pure culture of the *Diplococcus pneumoniæ*, which in all probability had assumed a pyogenic rôle, and the case was really one of sepsis due to this organism, which proved fatal.

In some of the cases of streptococcus pneumonia, as pointed out by Finkler, there is no expectoration at all.

In conclusion attention should be called to the fact that streptococcus pneumonia may simulate other diseases as well as lobar pneumonia. In a series of cases observed by Wasserman practically all had been sent to him with a suspicion of tuberculosis, and in some of Finkler's cases the resemblance to typhoid fever was very striking.

Rapid Recovery from Dry Pleurisy by Treatment with Iodide of Potassium.—L. Jacquet and Luzoir have observed three remarkable cases of resolution in dry pleurisy from the action of iodide of potassium. In one of them especially the friction sounds were extraordinary in their intensity and could be heard quite a distance from the thorax. These bruits disappeared in some days under the exclusive influence of this drug. The phlegmasia dated back three weeks, and the loud sounds extended over a large part of the right pleura. Iodide of potassium was administered at first in the dose of one gram and two days later pronounced improvement was evident. The treatment was continued with increasing improvement. Although this method is not entirely new, it deserves to be emphasized.—*Le Bulletin Médical*

REPORT OF THREE EPIDEMICS OF MEASLES, WITH PARTICULAR REFERENCE TO KOPLIK'S SYMPTOM AND ITS RELATION TO THE RASH AND THE INITIAL FEVER.*

By CHARLES J. DILLON, M.D.

NEW YORK

Ten years ago Koplik[1] first published his observations on the occurrence of a buccal eruption in measles, and, fully conscious that this is a late hour to attempt to supplement his studies, it is only for whatever of interest you may find therein that I wish to present the following statistics compiled from the records of three epidemics of measles in institutions for children.

The diagnostic value of Koplik's symptom seems to be quite generally conceded by the pediatrists of America and England, but not by any means so well credited by the French and German diagnosticians, if we are to judge from the communications on the subject in the technical periodicals for the last three or four years. An idea of the confusion which exists concerning the value of Koplik's symptom may be formed from a brief consideration of the recent observations of a few prominent investigators.

In England, Balme,[2] in the fall of 1904 published his observations of 214 cases of measles, in which he found the spots 209 times; in 95 cases examined in the prodromal stage they were present in 93, an unusually favorable report. Although English physicians as a whole have regarded Koplik's symptom with more favor than have those of the continent, it is worthy of note perhaps that as late as January, 1904, Eustace Smith,[3] in describing two cases of second measles infection, did not include observations of the buccal mucosa for this diagnostic sign.

About the same time Variot,[4] writing from Paris, asserted that the buccal eruption described by Koplik was of very doubtful value as an early diagnostic sign of measles, and claimed that the majority of his associates in the Société de Periatrice agreed with him.

Manassa[5] had stated, a few months previously, that he believed the spots to be a very valuable diagnostic sign and present in the majority of cases; curiously, though, he describes the spots as occurring on the palate as well as on the mucosa of the cheeks and lips, a description which does not agree with that of Koplik.

Aronheim,[6] on the other hand, in July, 1903, from his studies of 150 cases, many of them in the prodromal stage, concluded that Koplik's symptom was of no great value, he having found it only in 9 cases.

Müller,[7] in 1904, reported his observations during an epidemic at Marburg, where he found the symptom in 134 out of 166 cases examined; he recorded the observations of Perkel, who found the spots in 32 out of 33 cases examined in the prodromal stage, and in 67 out of 92 cases examined in the eruptive stage. Müller also noted the observations of Rolly, who found the spots in 67 out of 78 cases, in 24 of which they were seen from six hours to four days before the skin eruption.
